Sensitivity of Whole Body MRI Experiments

David I. Hoult

Winnipeg, MB, Canada*

1 INTRODUCTION

Surprisingly, the signal-to-noise ratio of a routine, clinical proton NMR image is governed by parameters that are somewhat subjective, and therefore difficult to assess. Concomitantly, optimizing the amount of diagnostic information that can be extracted by NMR imaging in a given time is fraught with difficulty and uncertainty. The subjectivity arises from the juggling of a number of often ill-defined variables, and from the fact that the end product of the experiment is not a spectrum, as in conventional NMR spectroscopy, but a picture. Both the variables and the picture are manipulated and interpreted in the light of substantial experience and with all the extra information that such experience brings to bear. Thus, for example, imaging parameters that produce ‘perfectly acceptable’ images from one patient may produce ‘images with artifacts’ from other, and the removal of these artifacts, at the whim (in the eyes of an untutored observer) of the viewer, may entail a reduction of image signal-to-noise ratio, but an increase of information. In the light of difficulties such as these, and the huge impact that magnetic resonance has had upon the discipline of radiology, the subject of imaging sensitivity is here treated separately from the more general topic of *Sensitivity of the NMR Experiment*. However, the present discussion builds upon the foundations laid in that article, with its relatively ‘firm’ conclusions, which the reader is therefore encouraged to read before becoming immersed in the complexities of the present analysis—notwithstanding its being only a brief overview aimed at routine imaging with 90° and 180° pulses at field strengths of 1.5 T or less.

To summarize the conclusions of *Sensitivity of the NMR Experiment*, it was shown that, following a 90° rf pulse, the voltage induced in a receiving coil by a small volume’s precessing nuclear magnetic moment could easily be calculated, provided the magnetic field that would be created at that volume by unit receiving coil current was known. Thus the signal (the free induction decay or FID) from a volume element (a ‘voxel’) in an imaging experiment can usually be found without difficulty. However, it was also shown that the random voltages (‘noise’) present in the receiving coil were somewhat more difficult to calculate, being associated with the resistance of the coil conductor and the electrical conductivity of the sample. As human tissues exhibit a range of conductivities, we shall be particularly interested in the latter type of noise, for the Brownian motion of electrolytes in the body induces random voltages in the receiving coil that usually predominate over the voltages associated with Brownian motion of the coil’s electrons. Finally, it was also shown that once an NMR protocol was run repeatedly, the accumulated signal became a

function of the longitudinal relaxation time T_1 of the sample. Thus, our aim in the present article is to extend these results to estimate the sensitivity of the whole body imaging experiment, particularly as a function of magnetic field strength, while introducing those additional factors, such as spatial resolution and power deposition, that are unique to the imaging experiment.

Underlying all the arguments to be presented is an analytical technique based upon the principle of superposition. The end result of most imaging experiments is the production of one or more large matrices of data (typically 256×256), where the row and column positions correspond to grid coordinates (u, v) within the sample plane or ‘slice’. Now such a matrix is most fruitfully examined (at least, by a human) not by scrutiny of its individual numbers (which are functions of amount of hydrogen, relaxation times, etc. at the corresponding spatial position), but rather by causing the numbers to modulate, according to a given law, the brightness of a video display. Once again, the matrix row and column positions correspond to grid coordinates—in this instance on the video screen. Thus, via the intermediary of the data matrix, there is a direct correspondence between position on the screen and position in the sample—there is an image, which is much easier to appreciate than a large matrix. Now the content of each matrix element is a measure of the signal emanating from the corresponding spatial position, and, ideally, each signal would come just from a cuboidal volume, the voxel, associated with that position. (In practice, the voxel is not so well defined—it is fuzzy round the edges, and overlaps its neighbors a little.) The process of spatial selectivity that allows the multitude of signals from different parts of a person to be sorted into their volumes of origin, is, of course, the essence of the imaging experiment (see *Image Formation Methods*). However, because the latter is a linear process, we may take the stunning liberty, right from the beginning of our analysis, of ignoring the vast majority of the signals and concentrating our attention upon the signal from a particular voxel of interest! We may then follow that signal, through all the indignities to which the imaging experiment subjects it, to find the final matrix element associated with the voxel. We may also find how the indignities affect the noise, and thus arrive for our voxel at a measure of its signal-to-noise ratio in the image. This then will be our course, with various digressions and comments as necessary.

2 FREE INDUCTION DECAY SIGNAL AND NOISE

With the above philosophy in mind, consider first a free induction decay signal (maybe in the form of an echo) received by a coil wrapped around a portion of the human body, for example, the head.^{1,2} The signal is from a voxel of volume dV subject to a 90° pulse, at a spatial position defined by Cartesian coordinates (u, v, w). Let the proton magnetic moment in the voxel be initially $d\mathbf{m} = M_0 dV \mathbf{z}$ where $\mathbf{z}$ is the unit vector in the z direction, and M_0 is the spatially averaged equilibrium magnetization ($\langle M_0(u, v, w) \rangle$) of the voxel. Using the principle of reciprocity, it may be shown [see equation (5) of *Sensitivity of the NMR Experiment*] that, following the pulse, the precessing magnetic moment $d\mathbf{m}$ induces in the receiving coil a voltage $d\xi$ given by

$$d\xi = 2\pi\nu_0(\tilde{B}_{1xy}M_0 dV) \exp(-t/T_2) \cos(2\pi\nu_0 t + \phi) \quad (1)$$

where ν_0 is the Larmor frequency, $\tilde{B}_{1xy}$ is the field at the voxel, parallel to the (x,y) plane, that *would* be produced if a current of 1 A at the Larmor frequency were passed through the receiving coil, T_2 is the transverse relaxation time of the elementary volume, and ϕ is a phase determined by the imaging protocol. As M_0 is proportional to the main field strength B_0 [see equation (1) of *Sensitivity of the NMR Experiment*], the amplitude of the FID is proportional to the square of B_0 , via the Larmor relationship $2\pi\nu_0 = \gamma B_0$. At the risk of stating the obvious, we emphasize that the signal from a voxel is directly proportional to the volume of the voxel, and therefore proportional to the cube of voxel side, or spatial resolution. This strong dependence is easily forgotten when one is deep in the intricacies of imaging, but can return to haunt one. That little factor-of-2 improvement in spatial resolution can lead to an order-of-magnitude loss of sensitivity!

As was shown in *Sensitivity of the NMR Experiment*, the noise induced in the receiving coil by a conducting sample may also be estimated with the aid of the principle of reciprocity.^{1,3} Experience shows that with a well-designed head coil, this noise dominates the noise associated with the coil's resistance at frequencies above about 8 MHz, while with a good body coil, the same is true above approximately 4 MHz.⁴ (Hence, there is little point at the frequencies usually used in imaging, 20–70 MHz, to attempt to cool head or body coils, for the improvement in performance will be negligible.) Some idea of the magnitude of the induced noise may be obtained by finding the power that would be deposited in a sphere of the tissue under consideration, by a homogeneous, on-resonance, radiofrequency transmitting field parallel to the (x,y) plane. Assuming this B_1 field is produced by an RMS current I in the receiving coil, the power deposited when the wavelength within the sphere is considerably greater than the latter's radius is^{1,3}

$$W = I^2 R_m = \frac{8\pi^3 \nu_0^3 I^2 \tilde{B}_{1xy}^2 b^5 \sigma(\nu_0)}{15\gamma^2} \equiv \frac{64\pi^5 \nu_0^2 \nu_1^2 b^5 \sigma(\nu_0)}{15\gamma^2} \quad (2)$$

where R_m is the equivalent resistance in series with the receiving coil, b is the sphere's radius, γ is the gyromagnetic ratio, ν_1 is the nutational frequency of the rf field, and $\sigma(\nu_0)$ is the tissue conductivity. (Note the explicit inclusion of the conductivity's frequency dependence; σ is usually of the order of 0.4 S m^{-1} in the NMR frequency range, but can vary considerably.⁵) The noise in bandwidth $\Delta\nu$ is now easily found [see equation (9) of *Sensitivity of the NMR Experiment*] from the effective resistance R_m , and when we use it to find the signal-to-noise ratio (S/N) of the FID, we obtain from equations (1) and (2)

$$d\Psi_{\text{FID}} = \left\{ M_0(\nu_0) dV \left[\frac{15}{8\pi b^5 \sigma(\nu_0) k_B T \Delta\nu} \right]^{1/2} \right\} \times \exp\left(-\frac{t}{T_2}\right) \cos(2\pi\nu_0 t + \phi) \quad (3)$$

where k_B is Boltzmann's constant and T is the sample temperature (310 K). This is a remarkable equation in that all dependence upon the field $\tilde{B}_{1xy}$ has vanished. The sample determines its own 'intrinsic' signal-to-noise ratio by its effective size

(radius b) and composition [$\sigma(\nu_0)$ and $M_0(\nu_0)$]. Thus, while in no way can a sphere of tissue be considered a good approximation to the human head or torso, we would expect the S/N associated with a voxel in the head to be considerably better than that for a voxel in the torso (say, by a factor of approximately $1.5^{\frac{5}{2}} = 2.75$), while a body scan of a pregnant patient would have relatively poor sensitivity. We might also expect the direction of the $\tilde{B}_1$ field to influence the S/N when the sample is asymmetric, for the effective value of b then depends on orientation. Further, the advantages and limitations of using a surface coil, with its very small effective value of b , have been discussed in *Sensitivity of the NMR Experiment*. Thus, in a set of experiments aimed at determining the validity of equation (3) and the magnitude of the term in braces,⁴ it has been shown that for water in a human head, with a typical receiving coil and a 90° pulse, over the range 5–80 MHz, the intrinsic S/N ratio is

$$d\Psi_{\text{FIDhead}} \approx \left[440 \frac{\nu_0 dV}{(\Delta\nu)^{1/2}} \pm 10\% \right] \times \exp\left(-\frac{t}{T_2}\right) \cos(2\pi\nu_0 t + \phi) \quad (4)$$

while for the torso, with the B_1 field from a typical coil running laterally,

$$d\Psi_{\text{FIDtorso}} \approx \left[2100 \frac{\nu_0^{0.8} dV}{(\Delta\nu)^{1/2}} \pm 60\% \right] \times \exp\left(-\frac{t}{T_2}\right) \cos(2\pi\nu_0 t + \phi) \quad (5)$$

Note that ν_0 is in hertz and dV in cubic meters. On the other hand, with an anterior–posterior B_1 field, it was found that the amplitude of equation (5) was roughly halved, bearing out the assertions concerning the shape of the sample. At first sight, it might appear odd that the coefficient in equation (4) is less than that in equation (5)—until it is remembered that the equations are only valid in the range 5–80 MHz. However, the interesting facet of equations (4) and (5) is their differing frequency dependences, attributable directly to the conductivity frequency dependences of the various tissues subject to the probe $\tilde{B}_1$ field. Note too the large percentage range allowed in the values: not error in the measurements, but rather the range of values likely to be encountered, given the great variety of the human form.

An offshoot of these measurements was an estimate of the power W [equation (2)] needed to produce a given transmitting B_1 field for the pulses. The power is deposited overwhelmingly in the patient in the form of heat from rf eddy currents, and general agreement with equation (2) was found. Thus, for the head,

$$W \approx 4.8 \times 10^{-20} \nu_0^2 \nu_1^2 \quad (6)$$

while for the torso with an anterior–posterior field,

$$W \approx 3 \times 10^{-21} \nu_0^2 \nu_1^2 \quad (7)$$

We shall encounter the rf power deposited again later in the article, but the reader is correct in assuming that this power is potentially dangerous. It is the only known hazard associated

with routine imaging. (See *Health and Safety Aspects of Human MR Studies*).

3 THE FOURIER TRANSFORM

The expectation aroused by the confirmation of theory contained in equations (4) and (5) is that the S/N of a brain image should improve linearly with field strength. Concomitantly,³ we expect the power absorbed in the head of a patient to increase as the square of the field strength for a given nutational frequency (i.e., pulse width and strength). For the torso, we might expect the sensitivity to increase somewhat more modestly, and the power deposited to increase more dramatically. An image's information content, however, is dependent not just upon intrinsic S/N, but on other factors too—primarily the resolution, the chemical shift range δ_H , and the relaxation times T_1 and T_2 , which are functions of frequency. We must therefore consider how FIDs [and, in particular, the FID from our chosen voxel at position (u, v, w)] are utilized in an imaging experiment involving these factors, and it is at this juncture that uncertainty clouds the analysis.

With most imaging techniques, each FID or echo in an imaging protocol suffers Fourier transformation as described in *Sensitivity of the NMR Experiment*, as the first stage in image formation. Now the essence of any imaging experiment (see *Image Formation Methods*) is a linear correspondence between Larmor frequency ν_0 and spatial position u during data acquisition:

$$2\pi\nu_0 = \gamma(B_0 + G_u u) \quad (8)$$

This correspondence is imposed by the user by impressing a known field gradient G_u (the 'read gradient') on the main (homogeneous) field B_0 . From the value of ν_0 , as determined from the 'spectrum' (the Fourier transform of the FID), the position u of our voxel is easily determined. However, suppose there is a small, additional field δB present, caused, for example, by nuclear shielding (a 'chemical shift'). From equation (8) we then have

$$u = \frac{2\pi\nu_0/\gamma - B_0 - \delta B}{G_u} \quad (9)$$

and there is a positional error of $du = -\delta B/G_u$ in the determined value of u and hence in the position of our signal in the final matrix of data, the image. If that error is more than a fraction of the image's 'spatial resolution' in u (i.e., the distance Δu equivalent to a shift of one picture element, a voxel side, or a jump of one matrix column—they are all approximately equivalent), it is potentially serious, for it represents a visible and possibly misleading misregistration of a portion of the image. However, to assess the potential for damage, we need to know both the range of any chemical shifts in the portion of the human body being imaged, and also the desired spatial resolution.

Now the hydrogen NMR spectrum of a region within a human, though complicated, is sometimes utterly dominated by only a single line—that of water, an ideal situation. Sometimes, however, it is dominated by a spectral structure, associated with both fat and water, covering a chemical shift range of roughly $\delta_H = 3.5$ ppm. (Thus, $\delta B = \delta_H B_0 \approx 3.5 \times 10^{-6} B_0$.) It

follows that, since we require the error $du \ll \Delta u$, the gradient must obey the inequality

$$\Delta u G_u \gg \delta_H B_0 = 3.5 \times 10^{-6} B_0 \quad (10)$$

In other words, if both water and fat are present in the portion of the body being imaged, the stronger the static field B_0 , the greater the read gradient G_u must be if we wish to render 'chemical shift artifacts' negligible. If this condition is disobeyed, water and fat signals *from the same spatial location* will appear at different locations in the image, while water and fat from *different* spatial locations may appear in the same image location. Thus, voids and overlaps are seen, with the potential for confusion and misdiagnosis, particularly if the viewer is inexperienced. If the only consequence of obeying equation (10) were an increase in engineering difficulty, it would be worthy of only passing consideration: we should note that extra expense was incurred, while a cynic might suppose that a salesman would therefore make sure his sale pitch would show only images that resulted from water alone. However, the employed gradient strength bears a direct relation to the 'acquisition window' (the time for which the FID is collected), to the resolution, and to the available S/N. To understand this statement, recall that in Section 4 of *Sensitivity of the NMR Experiment*, the S/N following Fourier transformation was optimized by collecting the FID for an optimum time $1.26T_2$, or, even better, by imposition of an exponential filter of time constant T_2 prior to transformation. Other filters, beyond the scope of this article, may also be advantageously imposed in imaging experiments, but no matter what method is employed to shape and define the data collection period, there is an 'uncertainty relation' linking the characteristic duration Δt of the time-domain data with the width $\Delta\nu$ of the ensuing spectral 'line'. ('Protuberance' might be a better appellation than 'line', since the latter implies smoothness and symmetry.) This relation is of the form

$$\Delta\nu \Delta t \sim 1 \quad (11)$$

(A well-known example, wherein the duration Δt is naturally limited, is $\Delta\nu = 1/\pi T_2$ for a Lorentzian line.) Now the frequency width of the spectral 'line' that results from transformation of the FID of our voxel of interest determines the *spectral* resolution—how close in frequency two 'lines' can be while still being distinguishable. (This is the Rayleigh criterion from the theory of optics.) However, because of the synonymy of frequency and distance, courtesy of the imposed gradient G_u , spectral resolution is directly linked to spatial resolution. Thus,

$$2\pi\Delta\nu = \gamma\Delta u G_u \quad (12)$$

and

$$\Delta t \sim \frac{1}{\Delta\nu} = \frac{2\pi}{\gamma\Delta u G_u} \quad (13)$$

Hence, from equation (10),

$$\Delta t \ll \frac{2\pi}{\gamma\delta_H B_0} = \frac{1}{\delta_H \nu_0} = \frac{2.86 \times 10^5}{\nu_0} \quad (14)$$

In other words, if chemical shift artifacts are to be avoided, not only must the read gradient increase with field strength, but the effective data acquisition window Δt must also become shorter and shorter. Once Δt becomes much less than T_2 , the S/N of the Fourier transform data begins to diminish rapidly—we are throwing away most of the FID signal and just using its beginning. With a typical value of T_2 for water in tissue of 50 ms, this transition occurs above approximately 6 MHz. Thus, for example, when imaging with a 1.5 T machine ($\nu_0 = 64$ MHz), equation (14) states that the data acquisition window Δt should be much less than 4.5 ms. Not surprisingly, the interpretation of ‘much less than’ can range from the pedantic to the flagrantly false, depending on the importance—commercial, diagnostic or scientific—placed upon the image sensitivity and chemical shift artifacts. Concomitantly, Δt is a variable of some importance that is frequently overlooked. However, once $\Delta t \ll T_2$, from equation (3) and (14), and from equation (15) and (16) of *Sensitivity of the NMR Experiment*, the S/N of the frequency-domain signal becomes

$$\begin{aligned} d\Psi_{\text{SP}} &= M_0(\nu_0) dV \left[\frac{15\Delta t}{8\pi b^5 \sigma(\nu_0) k_B T} \right]^{1/2} \\ &\ll M_0(\nu_0) dV \left[\frac{15}{8\pi \delta_H \nu_0 b^5 \sigma(\nu_0) k_B T} \right]^{1/2} \end{aligned} \quad (15)$$

while the resolution in the image becomes independent of variations in T_2 : a redeeming feature of the condition.

To summarize, we may conclude that for a head experiment, following a single 90° pulse, if chemical shift artifacts are to be avoided, the S/N ratio following Fourier transformation is

$$\begin{aligned} d\Psi_{\text{SPhead}} &= 440\nu_0 dV(\Delta t)^{1/2} \pm 10\% \\ &\ll 440 dV \left(\frac{\nu_0}{\delta_H} \right)^{1/2} \pm 10\% \\ &= 2.4 \times 10^5 dV \nu_0^{1/2} \pm 10\% \end{aligned} \quad (16)$$

Thus, the price paid for restricting the acquisition window to render negligible the chemical shift artifact, is that the sensitivity increases only as the square root of field strength. For the torso, the rate of increase is even less, being approximately as $\nu_0^{0.4}$.

To recoup this loss and fulfil our initial expectations, Hahn echo formation, using a number of 180° pulses, is needed. Images formed from each echo of a Carr–Purcell sequence may then be coadded [with weighting as $\exp(-t/T_2)$] to recover the lost sensitivity, and, as an added bonus, T_2 information may also be obtained. However, as we shall see, the power deposition in the patient is then substantially increased, and, further, the use of the sequence in a multislice experiment is not trivial. Other possible strategies include the use of chemical shift imaging techniques to give separate fat and water images (see *Chemical Shift Imaging*), or presaturation of either water or fat magnetization to remove its influence. However, chemical shift methods at least double the time taken to get an image, while presaturation demands excellent B_0 field homogeneity.

4 FROM TRANSFORM TO IMAGE

4.1 Signal-to-Noise Ratio

One FID does not an image make, and, with the exception of certain fast imaging methods (see *Echo-Planar Imaging*), data must usually be garnered from a prescribed number of FID’s or echoes. Typically, that number is related to one of the dimensions of the image matrix (e.g., 256), but we need not inquire too closely into the details—the important point for our analysis is that a minimum number of repetitions is required. (The protocol may then be repeated, and images effectively co-added if better S/N is wanted.) This subject had been examined in some detail in *Sensitivity of the NMR Experiment*, and Figure 5 of that article shows a contour plot of relative sensitivity versus flip angle and repetition rate. (For convenience, the plot is included in Figure 1 of the present article.) However, 90° pulses are mostly used in imaging protocols, and it may be seen that with a repetition period of $1.26T_1$, only about a 10% loss in sensitivity is suffered thereby. However, if T_1 changes, the length of time taken to collect the 256 FIDs must also change if we wish to maintain sensitivity. In short, the T_1 of the region of interest in the patient is the gold standard by which the repetition period TR must be judged. It follows that if we are to further our examination of signal-to-noise ratio, we must know how T_1 varies with tissue type and frequency. There are two reviews of the pertinent literature,^{6,7} and each shows that in the frequency range 1–100 MHz, T_1 for most tissues can be modeled in the form

$$T_1 \approx \zeta \nu_0^\eta \quad (17)$$

where the constants ζ and η are contained in brief summary in Table 1. An inescapable conclusion, then, is that as we increase the field strength, the minimum time taken to build an image increases as per equation (17) unless the imaging protocol is changed for some reason. The gains reaped as this increase in imaging time is suffered are that (i) the expected increase in S/N as $\nu_0^{1/2}$ (or as ν_0 if chemical shift artifacts are ignored or multiple echoes are used) is realized, and (ii) as the ratio $T_1/\Delta t$ increases with increasing field, so multiple slice methods gain in their ability to produce more cuts. (This improved ability is usually only of consequence at the lowest fields, and we do not consider it further.) However, in all fairness, we must ask how much the S/N of a low-field image could be improved if we were to allow for its acquisition the same time taken, perforce, at high fields. For example, if the minimum time T_{min} we are forced to take to acquire a scan at

Table 1 Tissue Longitudinal Relaxation Times T_1 ($\approx \zeta \nu_0^\eta$)^a

Tissue	ζ	η

Liver	0.00052	0.38
Skeletal Muscle	0.00045	0.42

^aDerived from Bottomley et al.;⁶ T_1 in s and ν_0 in Hz.

Figure 1 Normalized signal-to-noise ratio Ψ and relaxational contrast-to-noise ratio $\partial\Psi/\partial T_1$ in a repeated FID image as functions of effective flip angle θ and repetition period TR . The effects of any pulse used to produce an echo are neglected, and the plot is for a constant imaging time rather than a constant number of pulses. The C/N contours are the black lines, with values in bold print; the S/N contours are white lines, with values in plain print. The topologies of the two functions are similar, and it is possible to obtain simultaneous high absolute values. However, the plots are for constant hydrogen concentration, and therefore must be employed with care when there is a correlation between concentration (water content) and relaxation time T_1 : $\partial\Psi/\partial M_0$ and $\partial\Psi/\partial T_1$ have opposite signs and tend to cancel

80 MHz is four times longer (thanks to the frequency dependence of T_1) than that taken to acquire an equivalent image at 5 MHz then, by coadding four 5 MHz images (thereby also taking time $T_{\min}$), the S/N of the 5 MHz picture could be doubled. In short, a factor of $T_1^{1/2}$ has to be included in any assessment of image signal-to-noise ratios. Thus in a simple, S/N-optimized, 90° pulse, repeated FID imaging experiment (sometimes inaccurately termed a ‘saturation–recovery’ experiment) that avoids chemical shift artifacts and does not employ a Carr–Purcell multiple echo sequence, the head image S/N varies for fixed imaging time T as

$$\begin{aligned} d\Psi_{\text{Ihead}} &\approx 350\nu_0 dV \left(\frac{T\Delta t}{T_1} \right)^{1/2} \pm 10\% \\ &\ll 350 dV \left(\frac{T\nu_0^{(1-\eta)}}{\delta_H \zeta} \right)^{1/2} \pm 10\% \end{aligned} \quad (18)$$

Thus, taking gray matter with 80% water as an example,

$$d\Psi_{\text{Igray}} \ll 2.5 \times 10^6 dV \nu_0^{0.35} T^{1/2} \pm 10\% \quad (19)$$

and in 4 min at 64 MHz, an image with an S/N of 40:1 can have a voxel size of about $5 \mu\text{l}$, or in other words a resolution of about 1 mm in a 5 mm thick slice.

Summarizing, we have established the credentials of NMR imaging—resolutions of the order of 1 mm in 5 mm thick slices in times of the order of a minute or two. However, lest other

credentials be sought (‘Why not $1 \mu\text{m}$ in 30 s?’), the relationships in equations (18) and (19) are worthy of note.

1. We remarked earlier that the linear resolution Δu in an image, if all three dimensions are similarly scaled, is proportional to the cube root of the volume. Thus the time taken to attain a given S/N (whatever may be needed—normally in the range 16:1–64:1) is proportional to the inverse *sixth* power of the linear resolution Δu . It follows that if the S/N in an image is marginal, any idea of increasing resolution by imaging for longer should be promptly abandoned: the return is almost worthless. Keeping the resolution constant and imaging for longer (effectively coadding images) to improve the sensitivity is a reasonable course (improvement as the square root of time), but the overwhelming temptation must be to suffer the chemical shift artifacts and increase the data acquisition window!
2. The relationship between spatial resolution and field strength for constant S/N and imaging time is also weak, since $\Delta u \propto \nu_0^{(\eta-1)/6}$. For example, for gray matter, a 10-fold increase in field strength affords only a 25% improvement in linear resolution, unless one can be absolutely certain that only water is being observed.
3. Looking at the relationship between field and time for constant S/N and resolution, we see that $T \propto \nu_0^{(\eta-1)}$, and as the field is increased, so the time needed to gather and coadd multiple images decreases fairly rapidly—fewer additions are needed. However, once only a few additions are

needed, the use of imaging time T in the above arguments and equations is, in truth, a little artificial, since T must be granular—corresponding to say 128, 256, 2048, etc. FIDs, depending on the desired resolution and number of repetitions. Thus, as the field strength is increased and T diminishes, there will come a point at which one run of the imaging sequence, with its fixed number of FIDs, suffices. Thereafter, further increase in field strength serves to *increase* the time to collect that fixed number (thanks to the frequency dependence of T_1) while admittedly improving S/N.

Perhaps the overriding message of equations (18) and (19) is that the richest dividends come from innovative and minute attention to every detail of rf design. For example, a change of preamplifier from one with a noise figure of 4 dB to one with a noise figure of 1 dB, coupled with a switch to quadrature receiving coils, can improve linear resolution by 25%. It is perhaps for this reason that the literature is full of special coil designs for every conceivable part of the human body, even though there are, for the most part, no new design principles enunciated. Finally, there are those who would image other nuclei. The overwhelming obstacle to this desire is the paucity of elements other than hydrogen in the body. (Carbon-12 and oxygen-16 have no nuclear magnetic moments.) For example, the magnetization of metabolic phosphorus is less than 10^{-4} that of the body's hydrogen, leading *very* roughly from equation (19), to a voxel size in the head of the order of 30 ml at 64 MHz (3.7 T). Such a size is incompatible with the formation of a recognizable image.

4.2 Contrast-to-Noise Ratio

A common aspect of imaging is the desire to impart to the data a strong dependence on either relaxation time T_1 or T_2 , so that tissues with similar water content but different relaxation behavior can easily be distinguished. In this context, we draw a sharp distinction between absolute and relative contrast. The former relates to the *difference* in signal strength between two regions of differing relaxation, and is here our main concern. One's ability to distinguish that difference depends on its size relative to that of the noise in the image. However, it may be difficult to view the difference adequately in the context of the full image, since careful 'windowing' may be needed—the image brightness must go from dark black to full white over a small range of signal strengths, thereby blacking- or whiting-out detail in the rest of the picture. The *relative* contrast is simply the ratio of two signals, without consideration of the noise. If the *relative* contrast is large and the S/N is reasonable, there are no windowing problems, but only gross changes in relaxation behavior can be viewed.

We begin by considering absolute T_1 contrast, a measure of which for repeated FID imaging can be obtained by differentiation of equation (18) with respect to T_1 . Figure 1 is a normalized contour plot of absolute T_1 contrast-to-noise ratio (C/N) $\partial\Psi/\partial T_1$ versus flip angle and repetition period *for a fixed imaging time T* . Note that the contrast is negative, since a longer T_1 implies a greater degree of saturation and therefore a *reduction* in signal. It may be seen that for a 90° pulse, the point of maximum contrast (at $TR = 0.50 T_1$) is somewhat removed from that of maximum sensitivity at $TR = 1.26 T_1$. The relative values of sensitivity and C/N at these two rep-

Table 2 Normalized Maximum and Compromise Signal-to-Noise and Contrast-to-Noise Ratios in a Repeated FID Image^a

Experiment	TR/T_1	S/N	C/N
'Low-field' ^b	0.5	0.78	-0.92*
	0.81	0.87	-0.87
	1.26	0.90*	-0.50
'High-field' ^c	1	0.63	-1*
	1.75	0.83	-0.83
	∞	1*	0

^aFor a 90° pulse. 'Low-field' values are normalized to the maxima of the absolute values obtainable with a variable flip angle pulse. Contrast is negative because *increasing* T_1 results in *decreasing* signal.

^bImaging for a constant time, by adjustment of the number of repetitions of the imaging protocol. Usually applicable at fields of about 0.1 T.

^cImaging for a constant number of pulses, regardless of the time taken. Usually applicable at fields of about 1.5 T.

*Maxima of absolute values.

etition periods are shown in Table 2, and it may be seen that at the compromise value of $TR = 0.81T_1$, 87% of both the maximum possible S/N and C/N are obtained. This percentage is only a few points less than the maximum possible with a 90° pulse. As when considering sensitivity, the overall best T_1 contrast is obtained when repeating as fast as possible, albeit with a small flip angle θ obeying the equations

$$\exp(TR/T_1) = \frac{2 + \cos \theta}{1 + 2 \cos \theta}, \quad \cos \theta = \frac{2 \exp(-TR/T_1) - 1}{2 - \exp(-TR/T_1)} \quad (20)$$

While normal imaging methods employ 90° and 180° pulses, fast imaging techniques can take advantage of such low-flip-angle pulses.

When the C/N in an image is so good that multiple runs of the imaging protocol are not required, the optimum conditions are somewhat different. With a 90° pulse, the best T_1 contrast, as shown in Table 2, is obtained with $TR = T_1$, but then only 63% of the maximum sensitivity is garnered. A reasonable compromise is $TR = 1.75T_1$. An unfortunate aspect of imparting T_1 contrast by partial saturation is that there is often a correlation between tissue water content and T_1 : the more water, the longer is T_1 . The two variables then work in opposition, the greater saturation of the longer lived species tending to reduce its larger signal, thereby *reducing* contrast by the tendency to equate signal strengths. In these circumstances, an 'inversion-recovery' pulse sequence (see **Image Formation Methods**) is often employed, but, as shown in Figure 2, a considerable price is paid in both C/N and S/N. The lure of the inversion-recovery method is that the relative contrast (the ratio of the signal strengths of two species) can be very large, and thus the image is easily viewed. However, since both positive and negative signals can exist, a magnitude image can often not be used, and this can be both a considerable inconvenience and a trap for the unwary.

If we wish to determine how the contrast varies with field strength, we must have excellent knowledge of the frequency dependence of each T_1 of interest, and such data may be unavailable. Using the values for brain gray and white matter in

Figure 2 Normalized signal-to-noise ratio Ψ and relaxational contrast-to-noise ratio $\partial\Psi/\partial T_1$ in an inversion–recovery image as a function of inversion time (the time between the inverting 180° pulse and the following, signal-generating 90° pulse) and of recovery time TR (the time between the 90° pulse and the next 180° inverting pulse). The functions are normalized to the maximum values attainable under the conditions pertinent to Figure 1, the effects of any pulse used to produce an echo are neglected, and the plot is for a constant imaging time rather than a constant number of pulses. The C/N contours are the black lines, with values in bold print; the S/N contours are white lines, with values in plain print. The area with the lighter shading is where a positive correlation between hydrogen content and longitudinal relaxation time enhances T_1 contrast. It may be noted that the maximum absolute contrast in this area is obtained where the signal is weakest. Thus, the *relative* contrast of the inversion–recovery method can be very large. However, there is a considerable price to be paid, as may be seen from the values of the contours

Table 1, the absolute C/N is easily calculated at any frequency, but it is found that in going from 21 to 64 MHz (0.5 to 1.5 T), the increase in absolute contrast is only 12%. Again, it is stressed that this result is for the same imaging time at the two field strengths, and that chemical shift artifacts have been suppressed by an appropriate choice of data acquisition window.

Turning to T_2 contrast, dependence is easily imparted by generating an echo from the FID; indeed, most modern imaging methods use an echo anyway, since it helps to deal with a number of phasing problems. If we assume, as is usually the case, that $T_1 \gg T_2$, the repetition rate has almost no bearing on T_2 contrast. It may then be shown that to excellent accuracy for $\Delta t \leq 1.5 T_2$, the maximum absolute contrast is obtained when the acquisition window Δt is centered on echo time $TE = T_2$. However, this positioning can entail a loss of up to 63% in image sensitivity when $\Delta t \ll T_2$. On the other hand, the maximum *relative* contrast is obtained when the echo time is as long as possible, and the S/N in the image is then very poor indeed. The frequency dependence of T_2 (which is normally quite small) has little effect on the calculation once $\Delta t \ll T_2$. However, if multiple echoes are accumulated with an optimum filter, or if chemical shift artifacts are neglected, what little dependence there is, is reflected directly in the image sensitivity and contrast.

5 POWER DEPOSITION

In the preceding paragraphs, the discussion of the frequency dependence of an image's sensitivity and contrast has been dominated by the possible effects of chemical shift artifacts and the changing longitudinal relaxation time. However, there is an additional aspect to imaging that we dare not ignore, and that is the power deposited in the patient by the rf pulses. While a healthy individual can safely absorb 1 kW of infrared radiation for many minutes, our concern must be with a patient who may have cardiovascular or thermoregulatory problems. Further, it is obvious that the eddy currents induced in the body by the transmitter's B_1 field may be forced, at certain parts of the body (e.g., the shoulder blades), to flow through relatively thin layers of tissue, thereby generating so-called 'hot spots'. How the body handles such insults is not clear, but, in the context of this article, it is clear that there has to be a limit—and indeed, government agencies advise on the issue.^{8,9}

To attempt an assessment of the issue's seriousness, we must look at the factors that govern the rf pulses used in imaging. It is obvious that they must have a duration that is much less than T_2 , but they must also be powerful enough to cover the required bandwidth. While there may be problems with

main field inhomogeneity that require an increase in pulse bandwidth, such difficulties can usually be solved by the application of money—no amount of money can change the fundamental limit that is determined by the chemical shift range δ_H . If a composite image of water and fat is to be obtained, the exciting field must obey the inequality

$$\nu_1 \gg \delta_H \nu_0 \quad (21)$$

where ν_1 is once again the nutational frequency and ν_0 is the Larmor frequency. Needless to say, the meaning of ‘very much greater than’ is open to a wide variety of interpretations, and is also dependent on the type of pulse used. However, substitution into equations (6) and (7) to find the instantaneous power needed to produce the necessary field in the human body gives

$$W_{\text{head}} \gg 4.8 \times 10^{-20} \delta_H^2 \nu_0^4, \quad W_{\text{body}} \gg 3 \times 10^{-21} \delta_H^2 \nu_0^{4.4} \quad (22)$$

As usual, it is helpful to insert numbers, since with them we obtain the power specifications of the transmitter. Setting $\delta_H = 3.5 \times 10^{-6}$, we have at 10 MHz, $W_{\text{head}} \gg 6 \text{ mW}$ and $W_{\text{body}} \gg 230 \text{ mW}$, whereas at 64 MHz, $W_{\text{head}} \gg 10 \text{ W}$ and $W_{\text{body}} \gg 820 \text{ W}$. The very rapid increase with Larmor frequency demonstrated in these numbers, and in equation (22), shows that rf engineering problems become immense and expensive at fields not much larger than 1.5 T if composite imaging of water and fat is still to be entertained. Indeed, a typical specification for a transmitter at 64 MHz is already 10 kW.

Turning to the energy absorbed by the human body, we have already mentioned that 180° pulses are commonly used in imaging protocols. It is usually these pulses, rather than 90° pulses, that deposit the most energy in the patient. Now, with a rectangular envelope, the duration of such a pulse is $(2\nu_1)^{-1}$, and so the energy absorbed from each pulse is

$$E_{\text{head}} = 2.4 \times 10^{-20} \varepsilon \delta_H \nu_0^3, \quad E_{\text{body}} = 1.5 \times 10^{-21} \varepsilon \delta_H \nu_0^{3.4} \quad (23)$$

where ε ($\gg 1$) is a factor that takes account of the inequality in equation (21). In practice, pulses are often selective, which increases the energy a little, but this minor uncertainty is lost amid the greater uncertainty surrounding the factor ε , the size of the patient, etc. Now the recommendations of most governments concerning absorbed power P are related, among other factors, to the resting human metabolic rate (of order 100 W). (There are also recommendations concerning localized power deposition—the so-called ‘specific absorption rate’, SAR.) It follows from equation (23) that the number of 180° pulses per second that may be safely applied is

$$R_{180\text{head}} = \frac{4.2 \times 10^{19} P}{\varepsilon \delta_H \nu_0^3}, \quad R_{180\text{body}} = \frac{6.7 \times 10^{20} P}{\varepsilon \delta_H \nu_0^{3.4}} \quad (24)$$

For example, consider imaging at 80 MHz on the torso. Let $P = 30 \text{ W}$, $\varepsilon = 3$, and $\delta_H = 3.5 \times 10^{-6}$. Then $R_{180\text{body}} = 2.6$, which is highly restrictive. Such a value would prohibit, for example, a single echo, multislice experiment. We may manipulate the factor ε in equation (24) or justify to ourselves a little more power, but the overwhelming dependence in the equation is upon Larmor frequency. A small lowering of frequency makes a large difference to the flexibility and versatility of the equipment. Turning this statement about, even if our estimates

of power deposition are considerably in error or we manage to invent a pulse where ε can be honestly as low as 1, it will make little difference to the maximum frequency to which we can aspire. Put plainly, ‘high-field’ imaging with large-angle pulses presents serious problems for any method that aims to excite the whole chemical shift range encountered in the human body.

6 CONCLUSIONS

In any attempt to assess the imaging experiment, and in particular, the composite imaging of fat and water, which is the mainstay of clinical imaging practice, some objective criterion of usefulness is needed—a commodity hard to come by, for signal-to-noise ratio alone does not suffice. One possible approach to this dilemma is to realize that, with each 180° pulse used for echo formation, there is, in general, an associated and useful image. Thus, the ‘information’ potentially available to the radiologist can, to some degree, be measured by the number of 180° pulses that can be gainfully applied. We have already encountered an upper limit on that number as field strength increases, equation (24), caused by power deposition problems. However, there is another limit, as field *decreases*, caused by the fact that we presumably do not wish to apply 180° pulses more frequently than one every data acquisition period Δt . Thus, from equation (14), the maximum average rate at which they are likely to be applied is

$$R_{180\text{max}} = \lambda \delta_H \nu_0 \quad (25)$$

where the factor λ (< 1) allows for slower running, to accommodate the phase-encoding period, for example. To gather data at the maximum rate, a multislice, multiecho experiment would almost certainly be required. However, we note that the limits implied by equation (24) and (25) intersect at a frequency given by

$$\begin{aligned} \nu_{0\text{head}} &= 8.1 \times 10^4 \left(\frac{P}{\varepsilon \lambda \delta_H^2} \right)^{0.25} \\ \nu_{0\text{body}} &= 5.4 \times 10^4 \left(\frac{P}{\varepsilon \lambda \delta_H^2} \right)^{0.227} \end{aligned} \quad (26)$$

Below these frequencies, the rate of application of 180° pulses is limited by the long data acquisition window; and above, by the allowable power deposition. For example, with $P = 30 \text{ W}$, $\varepsilon = 3$, and $\delta_H = 3.5 \times 10^{-6}$, as previously, and with $\lambda = 0.5$, we have for the torso an intersection frequency of 32 MHz, allowing about fifty-six 180° pulses per second. These pulses could be used, for example, to obtain eight-slice, seven-echo images (if a slice repetition rate of one per second were used), thereby giving full T_2 information for each slice, and by weighted, coaddition of images, the full S/N unhampered by chemical shift artifacts. On the other hand, at both lower and higher frequencies, the maximum rate of application would be less.

The crux of the argument being presented here is that as field strength is increased in a *single slice experiment*, so a point slowly arrives at which resolution and S/N are those desired (without any need for repetition of the imaging protocol), and further field increases give little in return while

consuming some extra time. However, *for a multislice experiment* (and even more so for multislice, multiecho techniques), there comes a point at which power dissipation problems rapidly impose severe constraints, and versatility and flexibility are quickly hampered. It is a little like taking a walk over a gentle hill and suddenly finding a precipice on the other side! The reason for this behavior is clearly contained in equation (26): the frequency at which it occurs can be influenced but little by changing the allowable power deposition P , or by fudging one's notions of what are acceptable chemical shift artifacts, for these factors are raised to a small power—about 0.25. The numerical constants in the equations totally dominate, and they in their turn are dominated by the effective radius and conductivity of the sample. Thus, for the head, it may well be that a frequency of 70 MHz might maximize the information available; while for the torso, about 30 MHz might be best.

As the novelty of NMR imaging has worn off, and it has become a routine clinical tool, it has become clear that the bulk of the market has, in fact, settled for machines in the frequency range mentioned. Neuroradiologists tend to prefer the higher field strengths, for example, 1.5 T (64 MHz); many average radiology departments have settled for a strength of 0.5 T (21 MHz). The technology is reasonably mature, and its limits of resolution and sensitivity are understood, and have been, for the most part, reached. Having said this, the application of the technique is, at the time of writing, still expanding. However, it is salutary to think that if the amount of electrolytes in the body were considerably greater (thereby greatly increasing conductivity), or if hydrogen, like oxygen and carbon, had no nuclear spin, NMR imaging would have remained a curiosity.

1 INTRODUCTION

Since the inception of clinical MRI at the beginning of the 1980s, the rate at which a subject can be scanned—often denoted ‘patient throughput’—has been reduced by nearly an order of magnitude. Some of the improved scan efficiency is unrelated to a shortening of the actual data acquisition time, and can be accounted for by improvements in some of the ancillary procedures such as patient set-up, rf coil placement, scan parameter entry, prescan (MRI jargon for rf carrier selection and adjustment of transmit and receive gain), and advances in digital system architecture (shortening in reconstruction times, concurrence of data acquisition and reconstruction, etc.). The focus of this article, however, will be on techniques for reducing scan time, since it is this that determines patient tolerance. Scan times in excess of 5–10 min typically lead to image degradation from subject motion. Another strong motivation for shortening scan time is physiologic motion such as cardiac pulsation, respiration, and peristalsis. Clearly, if the data acquisition time could be lowered below the period of physiologic motion, the effect of motion unsharpness in the image data could effectively be suppressed. Many of the new applications, such as the assessment of organ function by monitoring the passage of a bolus of contrast agent¹ or the study of brain function by recording the response to stimuli,^{2–4} demand temporal resolution on the order of 0.1–1 s (see also *Contrast Agents in Whole Body Magnetic Resonance: An Overview*).

While many of the ideas for improved scan efficiency have been in existence for a decade or longer, they have become practical only recently, owing to engineering advances such as digital transceiver electronics (see also *Whole Body Magnetic Resonance Spectrometers: All-Digital Transmit/Receive Systems*) and gradient technology (see *Gradient Coil Systems*). A case in point is echo planar imaging (EPI), which was first conceived in 1977,⁵ but has only recently become practical.⁶ Finally, an increased data sampling rate typically exacts an

unavoidable penalty in signal-to-noise ratio (S/N). Since the minimum tolerable S/N is usually dictated by diagnostic criteria such as lesion detectability, increases in temporal resolution will usually have to be traded against spatial resolution.

This article briefly reviews the concepts underlying the most important classes of rapid imaging techniques, each of which is discussed in more detail in other articles in this Encyclopedia, referenced later. For a simple introduction to rapid MRI imaging techniques, the reader is referred to Wehrli.⁷

2 *k*-SPACE FORMALISM

We shall in the following resort to the classical *k*-space formalism⁸ (see also *Image Formation Methods*). In brief, data sampling occurs in reciprocal space, referred to as ‘*k*-space’ or the ‘spatial frequency domain’. For an object of spin density $\rho(\mathbf{r})$, ignoring relaxation, the spatial frequency signal $\rho'(\mathbf{k})$ is given by

$$\rho'(\mathbf{k}) = \int_{r_1}^{r_2} \rho(\mathbf{r}) e^{-i\mathbf{k}(\mathbf{r}) \cdot \mathbf{r}} d^3r \quad (1)$$

Here $\mathbf{k}(t)$ is the spatial frequency vector, expressed in units of rad cm⁻¹:

$$\mathbf{k}(t) = \gamma \int_0^t \mathbf{G}(t') dt' \quad (2)$$

where $\mathbf{G}(t')$ is the time-dependent spatial encoding gradient in vector format. Pictorially, the spatial frequency may be regarded as the phase rotation per unit length of the object experienced by the magnetization after being exposed to a gradient $\mathbf{G}(t')$ for some period t .

We further recognize from equation (1) that $\rho'(\mathbf{k})$ and $\rho(\mathbf{r})$ form a Fourier transform pair, and so

$$\rho(\mathbf{r}) = \int_{k_1}^{k_2} \rho'(\mathbf{k}) e^{i\mathbf{k}(\mathbf{r}) \cdot \mathbf{r}} d^3k \quad (3)$$

The path of the spatial frequency vector during execution of the pulse sequence is determined by the time-dependent gradient waveforms.

Since *k*-space is sampled discretely, sampling needs to satisfy the Nyquist criterion

$$\frac{1}{2} L_i k_{i,\max} = \frac{1}{2} N_i \pi \quad (4)$$

where $k_{i,\max}$ is the highest spatial frequency, L_i and N_i represent the field-of-view and number of data samples, respectively, and $i = x, y, z$. We can then write for the sampling interval Δk_i

$$\Delta k_i = \frac{k_{i,\max}}{\frac{1}{2} N_i} = \frac{2\pi}{L_i} = \frac{2\pi}{N_i \Delta L_i} \quad (5)$$

with ΔL_i representing the pixel size. The factor of 2 in equation (5) arises because we collect N_i samples from $-k_{\max}$ to $+k_{\max}$ or $\frac{1}{2} N_i$ samples from 0 to $k_{\max}$.

Since the data sampling time increases with the number of data samples, one obvious approach toward shortening the sampling time is to reduce N_i . It is readily seen from equation (5) that this can be achieved in two different ways. If we wish to maintain the pixel size, this will result in a reduction in the

field-of-view and thus an increase in Δk_i . Conversely, we may want to maintain the field-of-view, in which case Δk_i remains invariant but $k_{\max}$ is lowered, and thus pixel size is increased. In the latter case, we trade spatial resolution for a reduction in sampling time.

Further, since $\Delta k \approx \gamma \Delta t G$, the sampling interval Δt scales inversely with the amplitude of the spatial encoding gradients. Therefore, the duration of the spatial encoding process is governed significantly by the achievable gradient amplitudes. At a given resolution, the latter essentially determine what fraction of k -space can be covered following a single excitation (since the signal decays with time constant T_2). Therefore, the properties of the gradients, notably their amplitudes, and for many imaging sequences also their slow rates, are paramount in determining ultimate imaging speed.

3 CLASSIFICATION OF IMAGING TECHNIQUES

Most of the currently used imaging techniques use rectilinear k -space sampling, and as such may be regarded as descendants of the spin warp technique of Edelstein et al.,⁹ which itself is an outgrowth of Fourier zeugmatography, pioneered by Kumar, Welte, and Ernst.¹⁰ Since the latter is an embodiment of two-dimensional NMR spectroscopy,¹¹ conceptionally all rectilinear sampling techniques may be regarded as originating from 2D NMR. By contrast, projection–reconstruction imaging^{12–14} or imaging with nonperiodic time-varying gradients¹⁵ such as spiral scanning^{16,17} are not rectilinear sampling techniques, since the k -space path is non-Cartesian.

Common to all rectilinear k -space sampling techniques are two distinct phases of spatial encoding, a first period during which a gradient G_y is applied whose time integral determines k_y and during which no sampling occurs, followed by a second period during which a gradient G_x is applied while the free precession signal is sampled, resulting in a line k_x . The former is typically called ‘phase encoding’ and the latter ‘frequency encoding’. In this manner, a 2D k -space grid is sampled by incrementally stepping the amplitude of the phase-encoding gradient. The concept can be extended to a third dimension by phase encoding along a second spatial coordinate to afford k_z , in which case k -space is three-dimensional. In both back-projection and spiral scanning, two or all three spatial encoding gradients are simultaneously active while data are sampled. A generic 3D spin warp pulse sequence and k -space map are shown in Figure 1.

4 VARIOUS EMBODIMENTS OF SPIN WARP IMAGING

4.1 Scan Time, Signal-to-Noise Ratio and Spatial Resolution

Except in those situations where k -space can be scanned in a period on the order of T_2 , such as in EPI⁵ or multiple pulse techniques,¹⁸ resulting in a series of consecutive echoes that can be individually encoded, only a fraction of k -space is typically scanned upon creating transverse magnetization, and the process repeated several times, each cycle affording another k -space segment. Longitudinal magnetization builds

Figure 1 (a) Generic 3D spin warp imaging with phase encoding on the x and y axes and frequency encoding on z . Hatched areas indicate the spatial frequency vector at time t (b). Amplitudes of phase-encoding gradients are arbitrary. During readout, a line k_x is scanned corresponding to intersection between the (k_x, k_y) and (k_x, k_z) planes (shaded areas)

up in a recurrent fashion between cycles of period TR (also called ‘pulse repetition time’). The data acquisition time T_{ac} thus scales with TR and the number of pulse sequence cycles, the latter being a function of the number of spatial encoding steps or k -space samples. It is customary to denote the frequency-encoding axis by x and the phase-encoding axis by y (or y and z , respectively, if phase encoding in an additional dimension is effected), with N_i ($i = x, y, z$) representing the number of data samples. Assuming further that during a frequency-encoding period a single line $k_{x,i=1,\dots,N_x}$ is sampled, T_{ac} to sample k -space is given by

$$T_{ac} = N_y N_z n TR \quad (6)$$

where n represents the number of sequence repetitions (also called ‘number of excitations’ in imaging jargon) at given values of k . At typical sampling rates, the sampling time for frequency encoding is on the order of 10 ms or less, and so does not appear in equation (6). It will, however, become critical in high-speed gradient echo imaging^{19,20} and EPI and its derivatives.^{21–23}

The scan time scales with the number of phase encodings (N_y in 2D, and N_y and N_z in 3D spin warp imaging), and thus a reduction in the number of phase-encoding samples entails a concomitant reduction in scan time. As previously pointed out, this can be achieved in two different ways: either by lowering $k_{\max}$ or decreasing sampling density $1/\Delta k$. The former lowers resolution, the latter leads to reduced field-of-view while preserving resolution [cf. equation (4) and (5)]. Thus, the term ‘matrix size’ is ambiguous, though in common parlance a change in matrix implicitly implies fixed field-of-view. The two different situations, each lowering data acquisition time of a 3D image acquisition by a factor of 4, are illustrated in Figure 2.

Let us now examine the S/N implications of the two different operations. The signal amplitude S scales with voxel size, i.e.,

$$S \propto \Delta x \Delta y \Delta z = \frac{L_x L_y L_z}{N_x N_y N_z} \quad (7)$$

Figure 2 Halving the number of phase and slice encodings (N_y , N_z) in a 3D spin warp acquisition can be achieved by reducing either the k -space area (a) or the sampling density (b), leading to lower resolution (a) or reduced field-of-view (b). Open circles represent skipped data samples

where the product $\Delta x \Delta y \Delta z$ expresses the voxel volume, the remaining parameters have previously been defined. Further, the noise-reducing effect of sampling leads to

$$S/N \propto \sqrt{N_x N_y N_z n} \quad (8)$$

and thus

$$S/N \propto \frac{L_x L_y L_z \sqrt{n}}{\sqrt{N_x N_y N_z}} \quad (9)$$

From equation (9), we conclude that halving the number of data samples N_y and N_z by halving $k_{y,\max}$ and $k_{z,\max}$, increases S/N by a factor of 2 (Figure 2a). Skipping alternate data samples, on the other hand, penalizes S/N by a factor of 8 since this operation halves the field of view for both L_y and L_z [equation (5); Figure 2b].

4.2 Slice Multiplexing and Multiecho Acquisition

In most embodiments of 2D spin warp imaging, the period comprising slice selection, phase encoding, and frequency encoding accounts for only a fraction of the TR interval. Therefore, minimizing the dead time by shortening the pulse recycle time seems to be a straightforward means of optimizing scan time. However, TR is typically dictated by contrast requirements. Shortening of TR leads to progressive saturation, and thus, in spin echo imaging at least, is incompatible with proton density and T_2 -weighted contrast. A solution to this problem was first conceived by Crooks et al.,²⁴ who introduced what is commonly called ‘2D multislice imaging’. By making the rf pulses slice-selective, only the spins in the slice of interest are stimulated. Adjacent slices are then excited in sequence without perturbing the steady state. The gain in efficiency achieved in this manner depends on TR , the echo time TE , and the time required for applying the spatial encoding gradients, and typically ranges from about 10 to 50. The second important innovation was the incorporation of Carr–Purcell echoes into spin warp imaging. In this manner, images with different contrast²⁵ can be derived from a single acquisition. It is obvious that adding echoes reduces the number of slices that can be interrogated in a given TR period. Both 2D multislice and multiecho spin warp imaging, perhaps appearing trivial in hindsight, are, in historic perspective, among the most significant milestones in the quest for imaging efficiency.

4.3 Conjugate Synthesis

A salient property of k -space with implications for imaging speed is its conjugate symmetry, i.e.,

$$\rho(k) = \rho(-k) \quad (10)$$

This implies that two data samples corresponding to spatial frequencies k and $-k$ are identical. In principle, therefore, it suffices to acquire only half of k -space. In reality, however, the conjugate symmetry is often not perfect. Causes of deviations are phase shifts from magnetic field inhomogeneity and motion, which require appropriate correction of the raw

data before Fourier reconstruction²⁶ (see also *Partial Fourier Acquisition in MRI*).

As already pointed out, sampling in the k_y and k_z directions is much slower than sampling in the k_x direction. Therefore, by exploiting the redundancy in phase-encoding lines, scan time is halved. Halving imaging time by conjugation was described by Margosian et al.²⁷ and also by Feinberg et al.²⁸ Because the phase correction requires sampling of a small number of data lines on the conjugate half, the time saving is usually somewhat less than 50%.

4.4 Variable Flip Angle Imaging

In their seminal work on pulse Fourier transform spectroscopy Ernst and Anderson²⁹ showed that for a train of equidistant rf pulses, the extent of saturation can be controlled by adjusting the rf pulse flip angle α and further that the signal peaks for the condition

$$\alpha_{\text{opt}} = \cos^{-1} \exp(-TR/T_1) \quad (11)$$

where α_{opt} is the optimum pulse flip angle (also called the ‘Ernst angle’), which is valid provided that $TR \gg T_2$. It is readily recognized that flip angles $\alpha < 90^\circ$ are not compatible with the simple Hahn or Carr–Purcell imaging pulse sequence, since inversion of the residual longitudinal magnetization by the subsequent phase reversal pulse would lead to a steady state of very low magnetization. Haase et al.³⁰ modified the original spin warp technique in which a gradient echo is sampled and showed that in this manner TR could be reduced at least 10-fold relative to corresponding spin echo implementations, which may have prompted the authors to the acronym ‘FLASH’ (*fast low angle shot*). Other solutions to the problem involve the idea to restore the longitudinal magnetization with a second 180° pulse.³¹ An alternative solution is to select a flip angle so that $90^\circ < \alpha < 180^\circ$, followed by the usual phase-reversal 180° pulse.^{32,33}

In contrast to FLASH, the latter techniques provide true spin echo images in which the signal is attenuated as $\exp(-TE/T_2)$ rather than $\exp(-TE/T_2^*)$ as in FLASH.

The FLASH signal can readily be calculated from the Bloch equations to yield

$$S(TR, \alpha, TE) \propto \frac{1 - \exp(-TR/T_1)}{1 - \cos \alpha \exp(-TR/T_1)} \sin \alpha \times \exp(-TE/T_2^*) \quad (12)$$

For $\alpha = \alpha_{\text{opt}}$, equation (12) simplifies to

$$S_{\alpha_{\text{opt}}}(TE) \propto \tan(\frac{1}{2}\alpha) \exp(-TE/T_2^*) \quad (13)$$

In Figure 3(a), the relative S/N is plotted as a function of TR/T_1 for $\alpha = 90^\circ$ and $\alpha = \alpha_{\text{opt}}$, equation (12). In either case, a shortened data acquisition time exacts an S/N penalty, which, however, is less severe if the flip angle is optimized. At typical imaging field strengths (1 ± 0.5 T), mammalian tissue T_1 relaxation times span a range of about one order of magnitude (from about 0.3 s for fat to about 3–4 s for extracellular fluids). Hence, a compromise setting will have to be chosen for α . Figure 3(b) shows a series of images for which the flip angle was gradually increased, demonstrating the effect of increasing saturation and the progression from proton density to T_1 -weighting. Low flip angles emphasize structures with long T_1 , such as cerebrospinal fluid in the ventricles. It is noteworthy, however, that the flip angle for optimum contrast between two tissues of differing T_1 is greater than α_{opt} .³⁴

The assumption implicit in equation (12), i.e., $TR \gg T_2$ between successive rf pulses, may be invalid at high pulse repetition rates. As first described by Carr,³⁵ a steady-state situation arises for spins subjected to a train of rf pulses in inhomogeneous magnetic fields, with magnetization building up in a recurrent fashion from cycle to cycle. A similar situation applies in imaging, at least as long as the

Figure 3 (a) Signal amplitude as a function of TR/T_1 for repetitive pulses after attaining steady state: $\alpha = \alpha_{\text{opt}}$ (upper curve, with optimum flip angle indicated), and $\alpha = 90^\circ$ (lower curve), assuming negligible residual transverse magnetization. (b) Effect of increasing pulse flip angle in 2D gradient echo images ($TR = 0.3$ s), showing effect of gradual differential saturation

gradient moments are constant during successive cycles. In spin warp imaging, however, this latter condition is not satisfied, since the phase-encoding gradient is stepped in an incremental fashion. The ensuing cycle-dependent phase shifts cause intensity artifacts that have a positional dependence, since the phase depends on the spins' location on the phase-encoding axis.³⁶ If, on the other hand, the phase imparted by the phase-encoding gradient is unwound by a gradient of opposite moment prior to the next-following rf pulse,^{36,37} the spatial dependence of the steady state vanishes. Common acronyms for this modification to the generic FLASH pulse sequence are 'GRASS' (gradient recalled acquisition in the steady state) and 'FISP' (fast imaging with steady state precession).

From a tissue contrast point of view, it is often desirable to suppress transverse coherences. Application of spoiler gradients of varying amplitude has been found to be relatively ineffective for this purpose,³⁸ though schemes were later reported that provide some spoiling efficiency.³⁹ Nevertheless, a more effective means of eliminating the carry-over of transverse magnetization from previous cycles is to step the rf transmit and receive phase in constant increments from cycle to cycle. Although predicted by Crawley et al.³⁸ rf-spoiled gradient echo imaging was developed by Matt Bernstein and his colleagues in 1989, but, unfortunately, never published. The contrast characteristics of the two embodiments of FLASH are substantially different. In the high-flip-angle regime, GRASS affords images in which the signal scales as $T_2/(T_2 + T_1)$, hence favoring fluids, where $T_2 \approx T_1$ (as opposed to tissues, where $T_1 \gg T_2$). By contrast, with spoiling, the signal obeys equation (12).

4.5 High-Speed Gradient Echo Techniques

Combination of increased sampling frequency bandwidth and fractional echo sampling with partial Fourier processing,⁴⁰ reduction in the number of frequency-encoding samples, and other strategies such as truncated rf pulses permit shortening of pulse repetition times to 5 ms or less.^{19,20} The impact of reduced pulse repetition time on S/N is illustrated in Figure 3(a). These methods therefore need to be assessed in terms of the benefits and trade-offs they entail. Besides S/N, contrast is perhaps the single most important criterion for clinical utility. The typically unsatisfactory contrast inherent in high-speed steady-state techniques can be enhanced by means of magnetization preparation,¹⁹ discussed in more detail in *Whole Body Magnetic Resonance: Fast Low-Angle Acquisition Methods*. The underlying idea is to create a nonequilibrium situation by preceding the train of low angle rf pulses by an inversion pulse for T_1 -dependent contrast^{41–43} or driven-equilibrium pulses to achieve T_2 -weighted contrast.⁴⁴ Since, in this case, the magnetization evolves during scanning of k -space, effectively filtering the data in a manner determined by the spin dynamics, the usual sequential scanning from $-k_{\max}$ to $+k_{\max}$ is not optimal. Remembering that the signal components pertaining to $k \approx 0$ contribute most to contrast, it is necessary to acquire these data at the desired time point during magnetization evolution (e.g., when the signal from a particular tissue is nulled). These requirements can, for example, be reconciled with a k -space ordering scheme that has been called 'centric phase encoding',⁴² in which data collection starts at k -space center and proceeds outward.

Figure 4 Principle of segmented k -space acquisition in cardiac cine imaging. The RR interval is divided into time periods ('segments') of short duration, during which several lines k_y are encoded. The process is repeated during subsequent cycles until all lines are scanned

Finally, real-time implementations of fast gradient echo scanning are possible by confining images to a single spatial dimension. In this manner, projections can be displayed in real time at a frame rate of 100 s^{-1} as a scrolling bar, analogous to M-mode ultrasound, with possible applications in cardiology.⁴⁵ Another interesting idea based on fast gradient echo imaging is a method designed to track interventional devices. It consists of the consecutive generation of three orthogonal projections from a small pointlike object, followed by computation and display of its coordinates in a real-time mode.⁴⁶

A comprehensive review of short- TR imaging techniques has been given by Haacke et al.⁴⁷

4.6 Cardiac Gated Techniques

Except when the entire k -space can be covered in a small fraction of the cardiac cycle, such as in EPI,⁴⁸ data acquisition in cardiac imaging needs to be synchronized to the cardiac cycle. Therefore, it appears that the minimum scan time in 2D spin warp imaging of the heart is given as $N_y T_c$, with N_y and T_c being the number of phase-encoding samples and cardiac period, respectively. The inherent speed of the gradient echo then can be exploited to subdividing the cardiac period by collecting data at multiple cardiac phases, resulting in a series of temporally resolved images that can be played back in a movie loop, a technique that has been called 'cardiac cine' imaging.^{49,50} The minimum scan time can be considerably shortened (albeit at some cost in temporal resolution) if, instead of a single line k_y , multiple lines are scanned per cardiac phase, as illustrated in Figure 4. This modification, also termed 'segmented k -space acquisition',⁴³ permits shortening of the data acquisition time in cardiac cine imaging to 16–24 heartbeats,⁵¹ which is within the range of a breath-hold period, thus considerably improving cardiac image quality.

5 MULTILINE SCANNING TECHNIQUES

All previously discussed embodiments of spin warp imaging have in common that within one pulse sequence cycle, a single

data line is sampled. Additional echoes are merely a replication of the procedure affording images of increasing T_2 -weighting. An inherently more efficient approach makes use of the idea to exploit a plurality of echoes in such a manner that each echo affords a separate k_y line.

5.1 Echo Planar Imaging

In 1977, Mansfield first proposed what he termed ‘echo planar imaging’ (EPI), in which the entire 2D encoding process could be completed during a single FID. The fundamental principle underlying the technique is to oscillate the read gradient G_x in the presence of a constant gradient G_y .⁵ It is readily seen that in this manner, half of k -space is traversed in a zig-zag trajectory. The difficulties in reconstructing images from only half the data and nonorthogonal sampling grids were remedied with the introduction of pre-encoding gradients and discontinuous phase encoding.^{22,23} In this manner, entire images of 64×128 data samples could be obtained in as little as 50 ms at 2 T field strength.^{23,48} For an overview of the subject, the reader is referred to a review by Cohen and Weisskoff⁶ (see also *Echo-Planar Imaging*).

An interesting corollary of single shot EPI is that the pulse repetition time loses its meaning, since the data are collected in single sequence cycle. However, concatenation of individual acquisitions for the purpose of generating movies, for example, underlies the same restrictions as the conventional FLASH method, demanding adjustment of the rf flip angle to control saturation. Cohen and Weisskoff⁶ showed 16-frame cardiac movies obtained by acquiring complete images every 67 ms within a single heart beat. Unlike gated techniques, where each image data set, or fraction thereof, is collected during consecutive heart beats, the method is insensitive to variations in heart rate. In contrast to the high-speed FLASH-type methods, however, echo planar imaging puts far more stringent demands on instrumentation, in particular to amplitudes and slew rates of the gradients, which explains its currently limited diffusion. Some of these conditions are relaxed if only a fraction of k -space is scanned from a single echo train. For a detailed discussion of the subject, see *Echo-Planar Imaging*.

Finally, one wonders what S/N penalty this extraordinary scan speed exacts. At a given resolution, three parameters contribute to S/N:

1. sampling time ($S/N \propto \sqrt{T_s}$);
2. transverse relaxation losses ($S/N \propto \exp(-TE/T_2)$);
3. the fraction of magnetization available for signal creation (determined by saturation) ($S/N \propto f(TR, T_1, \alpha)$).

The following comparison may be instructive. Suppose a typical tissue such as neural white matter is scanned at 1.5 T field strength ($T_1 \approx 700$ ms, $T_2 \approx 75$ ms). Then consider a high-speed gradient echo acquisition with 128 phase encodings and 2 ms readout time, $TR = 5$ ms, $TE \approx 0$, operated at the optimum flip angle, which is 6.8° , and compare it with a single shot EPI with 50 ms total sampling time, performed such that $k_y = 0$ is sampled at $TE = 30$ ms. The results are summarized in Table 1. They imply a net advantage of about a factor of 5 in favor of EPI, defeating the common notion that shortened scan time inevitably exacts a S/N penalty.

Similar arguments in favor of EPI have been put forward by Cohen and Weisskoff.⁶ Such a comparison, however, does not withstand more rigorous scrutiny. Suppose we were to

Table 1 Comparison of S/N in Single Shot EPI and High-Speed FLASH; For Assumptions, See Text

	EPI	FLASH	$(S/N)_{\text{EPI}}/(S/N)_{\text{FLASH}}$
Sampling time (ms)	50	256	0.44
Magnetization	1	0.06	16.7
exp $(-TE/T_2)$	0.67	1	0.67
Net gain			4.9

repeat the EPI scan every 640 ms, i.e., the equivalent of the FLASH data acquisition time. This would mean that the longitudinal magnetization has only incompletely recovered, therefore requiring operation at the Ernst angle, which is 65° . Doing so reduces the transverse magnetization following the rf pulse to 0.64 [from equation (13)], thus lowering the relative S/N advantage of EPI to (a still substantial) factor of 3.

5.2 RARE

In 1986, Hennig introduced the spin echo counterpart of EPI,^{52,53} initiating a development with significant impact on clinical efficiency. Surprisingly, this work did initially not elicit broad interest. The perception that the images emphasized structures with long T_2 , thereby producing significantly T_2 -weighted images, prompted Hennig to dub his technique ‘RARE’, short for *rapid acquisition with relaxation enhancement*. While obviously highly efficient, the extreme T_2 weighting appeared to limit the method to specialized applications such as imaging of cerebrospinal fluid.

Besides scan time reduction by up to an order of magnitude, the current widespread clinical use of the method owes its popularity to its spin echo nature, i.e., being insensitive to magnetic field inhomogeneities. Equally important, however, is the almost unlimited latitude in image contrast RARE provides if implemented in a hybrid mode with only a fraction of k -space covered per echo train. It is interesting that the possibilities for contrast manipulation of the RARE sequence were already recognized by Hennig in his 1986 paper.⁵² By k -space weighting the echoes appropriately, Melki et al.⁵⁴ showed that virtually any arbitrary contrast is possible. For this purpose, they devised an algorithm for phase-encoding ordering while minimizing adverse effects from discontinuous sampling of k_y -space. For example, assigning early echoes to low spatial frequencies de-emphasizes T_2 weighting. The convolution of the data with the relaxation function, of course, may result in point spread function blurring, since high- k signals are attenuated.⁵⁵

Since each of the n echoes generates n lines k_y , the minimum data acquisition time is lowered n -fold. Nevertheless, when assessing the method’s efficiency in terms of scan time per image, one has to consider that the prolonged echo train reduces the number of slice locations that can be interleaved during the dead time following data collection. For example, at an echo train length of 250 ms consisting of 16 echoes, a $TR = 3$ s acquisition provides for fewer than 12 slice locations, rather than about 30 as for a conventional dual echo scan with a second echo time of 100 ms. Finally, Hennig showed that the per-unit-time S/N can be up to a factor of 100 higher in single shot RARE, which again emphasizes what we have seen for EPI, i.e., that increased scan speed does not inevitably penalize S/N. Therefore, the greatly improved efficiency can be traded

Figure 5 Three-dimensional RARE images of the lumbar spine: (a) axial section; (b) oblique reformation showing nerve roots

for improved resolution (by a factor of four in linear resolution) without adversely affecting S/N when compared with single line spin echo imaging. Further, it enables 3D imaging with all its benefits such as retrospective data rearrangement with image display in secondary planes, which was hitherto impractical in spin echo imaging because of excessive scan time. Examples of 3D RARE images are given in Figure 5. Finally, it has also been shown that RARE and EPI principles can be combined in such a manner that gradient echoes are interweaved into a spin echo train,^{56,57} and thus the efficiency is further augmented. (See also *Multi Echo Acquisition Techniques Using Inverting Radiofrequency Pulses in MRI*.)

6 OTHER METHODS OF SCANNING k -SPACE

An alternative k -space scanning technique that, like EPI, uses oscillating gradients is spiral scanning. As implied by the term, the k -space trajectory in this case is a spiral originating at the k -space center. Ahn et al.,¹⁶ who published the first spiral scan images, used a back-projection algorithm for reconstruction. Most of the more recent work is based on constant-velocity interleaved k -space spirals (as opposed to constant angular frequency), an embodiment that is credited to Macovski's laboratory¹⁷ (see *Spiral Scanning Imaging Techniques*). This scanning mode has the advantage that k -space is covered more uniformly and that the amplitude of the oscillating gradients is constant. Compared with EPI, the gradient amplitude and slew rate requirements are less demanding, and the technique has been found to be tolerant to flow-related dephasing, an observation that was attributed to the low gradient moments near the k -space center and the periodic simultaneous return to zero of all moments.¹⁷

Spiral scans require different reconstruction algorithms. Fourier transformation along the radial coordinate affords a series of projections, from which the image is obtained by filtered back-projection.¹⁶ Alternatively, the data can

be rearranged into a rectilinear grid by interpolation, thus allowing Fourier reconstruction¹⁷ (see also *Spiral Scanning Imaging Techniques*).

Another nonrectilinear sampling technique suited for high-speed imaging is projection imaging, where k -space is sampled radially in two or three dimensions by simultaneous application of two or three constant-amplitude gradients that are proportional to the sine and cosine of the projection angle. In this manner, a radial path is traced, starting at the center of k -space.^{13,14} k -space is covered by stepping the gradient amplitudes by incrementing the projection angle in successive sequence cycles. By selecting shallow rf pulses, the pulse sequence can be run at rates comparable to gradient echo spin warp imaging. Since sampling can start almost immediately following excitation, the technique is particularly suited for imaging short- T_2 tissues such as lung parenchyma⁵⁸ or imaging of nuclei with inherently short T_2 such as ^{11}B .⁵⁹ (See also *Projection-Reconstruction in MRI*.)

In summary, during the past two decades since its inception, MRI has revealed a wide spectrum of technical approaches for covering data space. Scan speed is a continuum ranging from milliseconds to minutes, with trade-offs between temporal resolution, S/N and spatial resolution. The rate at which k -space can be scanned is determined significantly by the imager's hardware, in particular the achievable amplitudes of the spatial encoding gradients and their switching rates, and the receiver's bandwidth. Besides intrinsic S/N, the ultimate scan speed may be limited by adverse bioeffects, notably peripheral nerve stimulation caused at increased dB/dt of the switched gradients.

Currently Professor of Radiologic Science and Biophysics, University of Pennsylvania Medical School. Approximately 95 publications. Current research specialty: NMR imaging of biomaterials, specifically trabecular bone.

Whole Body Studies: Impact of MRS

George K. Radda

University of Oxford and The John Radcliffe Hospital, Oxford, UK

1 INTRODUCTION

It is common to refer to MRS studies of humans as ‘whole body’ MRS, or, as indicated in the title of this article, ‘whole body studies’. This is a misnomer, since much effort is expended in obtaining MR spectra from a defined organ or even a defined part of the given organ and not from the whole body. The term arose because generally, though not exclusively, this kind of measurement is taken in magnets that can accommodate the human body. In the study of limbs and the head, this is not always necessary, and much human MRS has been done using magnets that only accommodate part of the body. This article is therefore about the impact of MRS in human investigations, but excludes discussion of work in which MRS is used to study samples from biopsies or body fluids of humans. Much of the human data is inevitably backed up, extended, or elucidated by parallel animal investigations. Although such studies have played an essential role in the development and evaluation of human MRS, they are not included in this article for organizational rather than conceptual reasons.

1.1 The Varying Aims of Human MRS

Following from the success of MRI as a radiological tool in clinical diagnosis, it is not uncommon to view MRS as just another extension of the technique for the characterization and description of pathology. Thus one aim is to find clinical applications that can contribute to diagnosis in a routine examination. It will be shown below that this aim is far from having been achieved, and it will be argued that, given the nature and cost of the technique, the major justification for using MRS rests elsewhere. The second main aim of MRS is to investigate the dynamics of normal human biochemical processes. It is necessary to ask, however, why it is important to study fundamental biochemical processes in humans when the same cellular mechanisms are likely to be operative in all mammalian species. Significant special aspects of human biology, among others, include the wide range of polymorphism that results in the biochemical heterogeneity, the nature of the immune system, the advanced central nervous system, and the ease by which the effects of training, adaptation and environmental factors can be studied in humans. In addition, developmental processes at the structural and biochemical level require direct human investigations. The most important of the

goals in MRS research is the study of the biochemical basis of human disease. Many human diseases have no useful animal models; the response to pharmacological interventions is often species-specific, and human morphology and anatomy has a unique influence on the expression and development of disease.

1.2 Approaches to Clinical MRS

A successful clinical study by MRS has several basic requirements:

- (a) to obtain well-resolved spectra from defined regions of human organs and tissues in a time acceptable to patients;
- (b) to obtain as much information as possible, and to assign and interpret the biochemical meaning of the spectra;
- (c) to use the biochemical information derived to advance clinical understanding or management.

(a) Localization strategies fall into two major categories: single volume selection and spectroscopic images obtained in the form of one-dimensional slices or with lower frequency as two- or three-dimensional data acquisition. The choice of the method used is often limited by the instrumentation provided by the manufacturer (different manufacturers emphasize their own preferred options). It would be desirable if the localization could be tailored to the nature of the clinical condition to be studied. This is likely to become increasingly the case. Since the majority of current human spectrometers are based primarily on advanced MRI systems, image guided localization is the common practice.

(b) There are instances where a single spectroscopic measurement provides valuable clinical data. In most instances, however, the information content of the study is considerably increased by the measurement of reaction rates either directly, or more generally, in response to some intervention or stress test. For example, almost all the investigations of muscle metabolism and energetics in disease rely on following changes in the concentrations of high- and low-energy phosphates and in the pH values in response to exercise (dynamic or isometric), and during the recovery phase after exercise. In organs such as the liver, stress might be induced by the infusion or oral administration of substrates (glucose, fructose, etc.), while the intervention of most interest in tumors could well be the therapeutic method that is being used.

In the human brain, sensory stimulation may be used in some measurements (e.g., glucose uptake¹) to provide regional activation. It is also possible that metabolic changes may be detected in responses to the administration of drugs that interfere with neurotransmitter release or function. Cardiac work can be increased by exercise (dynamic leg exercise or isometric hand grip) or by infusion of dobutamine.

The assignment of peaks in the spectra observed in vivo and their biochemical interpretation are largely based on extensive studies of cells, isolated organs, and animals. Spectral resolution and quantification often remain a problem, but progress is being made to replace measurements of metabolite ratios with derivation of absolute amounts or intracellular concentrations.

(c) Increasingly, the understanding of mechanisms of human disease should lead to the design and evaluation of new therapies. MRS, in the first instance, contributes to this process in a general sense. There are, at present, only a handful of specific

cases where a spectroscopic evaluation altered the management of a particular patient. Indeed, the view has been advanced by the present author that the success of MRS will be measured by how readily the expensive and technically demanding MRS study can be replaced by a relatively simple but perhaps less informative and more empirical test for following the clinical status of a patient. This view is based on the belief that if we can define the nature and extent of the disease from MRS studies, it should be possible to design tests that can be correlated.

1.3 What Nuclei?

The nuclei that have been used so far in human investigations are ^{31}P , ^1H , ^{13}C , ^{19}F , ^{23}Na , and ^7Li . This choice is often governed by the technology, i.e., relative sensitivities, ease of detection, resolution, and quantification. Since we now know that high-resolution spectra can be obtained from all these nuclei in human organs (with the exception of ^{23}Na , where only total, largely extracellular, Na^+ is measured), it is essential that their choice should be governed by the biomedical problems we wish to solve.

1.3.1 ^{31}P MRS

This is widely used to investigate cellular bioenergetics in vivo.² Essentially, the following parameters that relate to the energetics are measured: the relative and, more seldom, absolute concentrations of ATP, PCr, Pi, and hexose phosphate, and the value of intracellular pH, which is often equated with the production of lactic acid. The concentration of ADP is often calculated assuming that creatine kinase is at equilibrium. Following changes in these values with stress (e.g., exercise in skeletal muscle and heart), substrate infusion, or administration (e.g., fructose, galactose, and glucose) yields direct or indirect measures of specific enzyme activities or of rates of transport of substrates or ions (e.g., Na^+/H^+ exchange rates). Additionally, magnetization transfer has been used to measure the activities of creatine kinase in human muscle,³ brain,⁴ and heart,⁵ and in principle the activity of ATP synthase, so far only achieved in animal studies in vivo.⁶

In addition to the study of energetics, ^{31}P MRS can be used to follow pathways associated with the synthesis and degradation of phospholipids. Key molecules often detected include phosphoethanolamine and phosphocholine, which are intermediates in the Kennedy pathway of phospholipid biosynthesis, but may also be generated by specific phospholipase C catalyzed degradation of membrane phospholipids, perhaps involved in signaling pathways during cell proliferation. Other degradation products observed are glycerophosphorylcholine and glycerophosphorylethanolamine. In vivo, the resonances of these small metabolites may be obscured by the much larger and broader phosphodiester (PDE) signal arising from the phospholipids in the bilayers of membranes.⁷

1.3.2 ^{13}C MRS

This provides an extremely powerful approach, since, through the use of ^{13}C -enriched substrates, it can lead to measurements of individual reaction rates or fluxes through specific pathways.⁸ The formation and breakdown of muscle

and liver glycogen can be studied in this way.⁹ The sensitivity of ^{13}C detection is considerably enhanced by the proton observe carbon edit (POCE) method. This allows detection of the ^{13}C label in the ^1H spectrum with heteronuclear editing, thus obtaining the information in the ^{13}C spectra with the sensitivity of ^1H MRS. This technique, as well as direct ^{13}C measurements, has been used to observe the flow from $[1-^{13}\text{C}]\text{glucose}$ into the C-4 of glutamate via the tricarboxylic acid cycle in human brain.¹⁰

1.3.3 ^1H MRS

This is now widely used in clinical and physiological investigations, particularly of the human brain. Special techniques are required to suppress the water resonance, and in addition it is sometimes necessary to edit the spectra if specific components (e.g., lactate) are to be observed. The major metabolites that can be detected include *N*-acetylaspartate, glutamate and glutamine, creatine + phosphocreatine, and, under some conditions, lactate.¹¹ Additional signals are obtained from the so-called 'choline-containing compounds' (likely to represent a mixture of several substances), taurine and inositol phosphates.

Unlike the metabolites that are detected in the ^{31}P MR spectra, the components seen in ^1H NMR are not directly linked through major pathways, or in several instances have no established functional role. The lactate signal, however, represents a sensitive handle on anaerobic glycolysis. Knowledge of total creatine (from creatine and phosphocreatine) provides useful data when combined with measurements of phosphocreatine by ^{31}P MRS. *N*-acetylaspartate has been used empirically as a 'neuronal marker', though this remains to be established.

1.3.4 ^{19}F MRS

This is used for the measurement of the tissue concentration and metabolism of fluorinated drugs (e.g., the antidepressant fluoxetine in the brain)¹² or fluorinated agents like halothane.

1.3.5 ^7Li MRS

The unique use of lithium therapy in psychiatric patients is beginning to be studied by this technique, allowing the determination of brain concentrations and pharmacokinetics.¹³

In the discussion below, studies will not be classified according to the nuclei observed, but rather will be presented in relation to the investigation of physiological and pathological problems.

2 NORMAL HUMAN BIOCHEMISTRY

The distinguished Harvard physiologist Walter B. Cannon (1871–1945) coined the term 'homeostasis' to describe the coordinated physiological processes that maintain most of the steady state in an organism. The structural and functional features of the components of the organism are optimized to provide adjustments to the required performance of the system (input/output balance). Ultimately, cellular biochemical regulatory processes perform this function. In addition to short-term molecular control, the long-term response to chronically increased needs involves adjustments in the design properties of the system. Weibel¹⁴ introduced the principle of symmorphosis

and defined it 'as a state of structural design commensurate to functional needs resulting from regulated morphogenesis'.

MRS *in vivo* provides a unique way of studying control, development and adaptation, since it provides quantitative data about 'molecular integrative physiology' through the measurement of dynamics, structure and interactions within any part of the whole organism. While traditionally medicine is 'organ-oriented' and MRS is used to examine organs, the exciting aspect of the method is that it is particularly suited for the observation of coordinated bodily functions at the molecular level.

2.1 Control of Bioenergetics In Vivo

2.1.1 Skeletal Muscle

One of the fundamental questions in the understanding of bioenergetics *in vivo* is how the demand for ATP utilization is linked to increased supply of energy via oxidative metabolism and therefore to increased rate of oxygen delivery to the tissue. Oxygen delivery to the mitochondrion within the intact cells has four components:

1. the oxygen-carrying capacity of blood, i.e., the nature and amount of hemoglobin present;
2. the rate of flow of blood through major blood vessels;
3. capillary density and diffusion from the capillary to the mitochondrion;
4. the ability of oxyhemoglobin to release its oxygen, i.e., the dissociation of curve for oxyhemoglobin.

^1H NMR has been used to observe the ratio of oxy/deoxymyoglobin, since the chemical shifts of the proximal histidine resonance of the two forms are different.¹⁵ Indirectly, blood oxygenation can be measured through the effect of paramagnetic deoxyhemoglobin on the T_2 relaxation time of blood,¹⁶ although this effect has not yet been explored in studies of human muscle. It is believed to be partly responsible for the changes seen in the brain during sensory stimulation.¹

It is possible to link NMR studies to measurement of tissue oxygenation using infrared detection of oxy/deoxymyoglobin and hemoglobin. During exercise, the decrease in the oxy forms can be related to oxygenation, and the rate of recovery is a measure of the oxidative capacity of the system.¹⁷

While the various pathways involved in the energetics of skeletal and cardiac muscle are well mapped out, the way in which they are controlled in the intact cell is less well understood. NMR studies *in vivo* have contributed a great deal to our understanding of some of the control functions, particularly in skeletal and cardiac muscle.

In skeletal muscle, mitochondrial oxidation *in vivo* was shown to depend, in a hyperbolic manner, on the concentration of ADP, with a K_m of about $30\ \mu\text{M}$. This value is very close to that reported by Chance and Williams for isolated mitochondria. Three types of experiments have been performed to arrive at this conclusion.

1. Chance and his colleagues have shown that in a graded exercise protocol in which the work is measured with an ergometer, during performance going from rest (state 4) to exercise (state 3), the transfer function, as defined in Chance et al.,¹⁸ approximates a rectangular hyperbola (i.e., the plot of work against Pi/PCr is hyperbolic), giving a K_m for ADP of $28\ \mu\text{M}$. This follows from the fact that if there are no pH changes, as is the case in the relatively submaximal protocol

used, the Pi/PCr ratio is proportional to the concentration of ADP.¹⁸

2. It was shown that the ADP concentration reached at the end of exercise and the initial rate of phosphocreatine resynthesis during recovery in human arm muscle also follow the same relationship, giving a K_m value of $27\ \text{mM}$ and a $V_{\max}$ for the ATP synthesis rate of $43\ \text{mM min}^{-1}$.¹⁹
3. Measurements of the flux between ATP and Pi during steady state isometric muscle contraction using magnetization transfer in animal muscle give a direct indication of the relationship between ADP and mitochondrial oxidative phosphorylation.⁶

Recovery from exercise is a function of mitochondrial ATP synthesis.²⁰ It can therefore be thought of as an aerobic work jump, in which the rate constant of PCr recovery is a function of $V_{\max}$ for ATP synthesis, with the complication that the pH may also be recovering from a low value. As no work is done, the absolute rate of PCr resynthesis is an estimate of the oxidative ATP synthesis rate minus a small component of basal ATP turnover. The hyperbolic relationship between oxidation rate and $[\text{ADP}]$ can be used to estimate apparent $V_{\max}$ and mitochondrial K_m in the same way as in oxidative exercise.

The apparent $V_{\max}$ is a function of the density and capacity of working mitochondria and the supply of substrate and oxygen and is independent of muscle mass. A preliminary calculation for human forearm muscle suggests that the $V_{\max}$ calculated from PCr recovery kinetics is 60–70% of that predicted from the intrinsic activity and muscle content of mitochondria. A reduction in apparent $V_{\max}$ can be caused by an intrinsic mitochondrial defect or a reduction in mitochondrial density (e.g., heart failure) in arterial oxygen carrying capacity or arterial $p\text{O}_2$ or in muscle blood flow.²¹

The quantitative analysis of the energetic processes during exercise is more complex, since both oxidative and anaerobic glycolytic processes contribute to ATP synthesis while the ATP used against the work done depends on muscle mass and other parameters. In a detailed analysis of exercise performed at three levels of mechanical power output under ischemic and aerobic conditions, it was suggested that oxidative ATP synthesis was negligible during the first half-minute of aerobic exercise, and increased with a half-time of around 0.75 min, although the mitochondrial controller $[\text{ADP}]$ increased much more rapidly.²² Initial PCr resynthesis after exercise appeared to be an adequate estimate of oxidative synthesis at the end of aerobic exercise. The pH dependence of proton efflux inferred from analysis of recovery could be used to estimate ATP synthesis by glycogenolysis/glycolysis to lactic acid during aerobic exercise. Measurement of lactic acid production by ^1H NMR, which has been demonstrated as a possibility,²³ might be used to confirm these conclusions. The quantitative interpretation of ^{31}P MRS data from human skeletal muscle, which has many applications to the study of physiology and pathophysiology, and of muscle bioenergetics and proton handling, has been analyzed in detail.²⁰

^{31}P NMR is particularly suited for the examination of the relationship between work output and energetics *in vivo*. This has been achieved in animal models using, preferentially, sciatic nerve stimulation inducing tetani at different frequencies and with different time intervals. In humans, a variety of experimental protocols have been worked out. Some studies have used the steady state or graded work rate from a constant load

or a Cybex ergometer, while others have used force produced in an isometric contraction. Chance and co-workers have examined the relationship between reaction velocities (e.g., ATP utilization) and tissue work rates to the concentration of regulatory molecules in skeletal muscle.¹⁸ They examined the forearm muscle and measured values of Pi/PCr and the work by an ergometer in a graded metabolic load situation. They expressed the relationship between work and velocities as a 'transfer function', showing the hyperbolic relationship between velocity and Pi/PCr. The form of this transfer function varies between normal individuals and well-trained athletes, and can be used as an indication of exercise performance. Boska studied the ATP cost of force production in the human *gastrocnemius* muscle using ³¹P NMR and an exercise protocol of isometric maximum voluntary contraction, and estimated the contributions to ATP production from three different processes.²⁴ The rate of change of PCr was used to estimate ATP production rates from creatine kinase rates during exercise and from oxidative phosphorylation during the first 10 s of recovery. The anaerobic glycolysis was estimated from the rate of change of pH, from an assumed buffering capacity and hydrogen ion production stoichiometry. The results showed that by the end of 30 s of exercise, the total ATP production and ATP cost of force production had stabilized and remained constant until the end of a 2 min period. It was also shown that the ATP cost of force production is lower in the first second than at any time, or possibly that ATP production is underestimated at later time points.

2.1.2 ¹³C NMR and Glycogen

A major new approach to the study of substrate utilization in bioenergetics is provided by the use of ¹³C NMR and in particular in the use of ¹³C-enriched substrates, which can lead to measurements of individual reaction rates or fluxes through specific pathways (for a recent review of ¹³C NMR, see Cerdan and Seelig²⁵).

An important new observation for muscle investigations was that, in spite of its high molecular weight, glycogen is fully visible by ¹³C NMR in organs and tissues.²⁶ Thus the synthesis and breakdown of glycogen during muscle exercise can now be followed for the first time noninvasively in human muscles. There are many opportunities to study fundamental questions of the regulation of carbohydrate metabolism under a variety of conditions. One example of this was the pioneering study in which the rate of human muscle glycogen formation was measured in normal and diabetic subjects, using infused, isotopically labeled [1-¹³C]glucose and ¹³C NMR.²⁷ The important conclusions from these measurements were that

- (i) synthesis of muscle glycogen accounted for most of the total body glucose uptake and all of the nonoxidative glucose metabolism;
- (ii) in subjects with non-insulin-dependent diabetes, the rate of glycogen formation was decreased by 60% compared with the rate in normal controls.

2.1.3 Human Heart

Many of the same parameters can, in principle, be measured in heart muscle, and have indeed been studied in isolated and in vivo animal hearts. So far, only the PCr/ATP ratio as an index of energetics has been quantitatively measured in the human heart, using special localization or

spectroscopic imaging techniques (for a review see Conway and Radda²⁸). In normal subjects, the PCr/ATP ratio remained constant when the heart was stressed, either by an isometric hand grip exercise²⁹ or by a dynamic leg exercise performed in the prone position.²⁸ Thus, in the normal situation, the heart can adequately regulate its phosphates over a range of workloads. The results show that free ADP is not the primary regulator of increased ATP synthesis in the normal heart in these situations.

2.1.4 Brain Metabolism

Glucose is the main, and generally the sole, energy source for the brain. Thus measurement of the regional cerebral rate of glucose consumption together with that of oxygen consumption and regional blood flow has been used to describe brain energetics. Using radiolabeled compounds, in humans [2-¹⁸F]fluorodeoxyglucose accumulation and ¹⁷O uptake are followed by positron emission tomography.

Recently, largely as a result of work by Shulman and colleagues (for a review, see Shulman et al.¹) NMR spectroscopic methods have been developed for measuring regional metabolic parameters.

The kinetics of glucose transport in the human brain has been determined by measuring brain glucose concentration by ¹³C NMR at steady state as a function of plasma glucose concentration. Using a model for facilitated transport, values of $K_m = 4.9 \text{ mM}$ and $V_{max} = 1.1 \mu\text{mol g}^{-1} \text{ min}^{-1}$ were derived from the transporter. The maximal glucose influx was 3.6 times the normal glycolytic rate, showing that increases in energy demand can be accommodated by glucose transport. In addition, the concentration of glucose in the brain (about 1.2 mM) is well above the K_m for hexokinase, so that changes in plasma glucose will not change the hexokinase flux except at very low concentrations. The turnover rate of the brain glutamate pool can be measured by following the incorporation of ¹³C isotope from [1-¹³C]glucose into C-4 of glutamate on the first timing of the tricarboxylic acid (TCA) cycle. The isotopic flux has been measured directly by ¹³C NMR and by the proton observe carbon edit method. By fitting the results to a metabolic model, the rates of the TCA cycle can be determined, which gives a measure for the O₂ consumption rates. For the human occipital lobe/visual cortex, this was found to be $1.5 \mu\text{mol O}_2 \text{ g}^{-1} \text{ min}^{-1}$, a value close to that reported from PET studies.¹

Visual stimulation results in observable metabolic changes in the visual cortex that include increased lactate production (observed by ¹H NMR),¹ decreased brain glucose concentration,³⁰ and a change in the PCr/ATP ratio³¹ as seen from ³¹P NMR.

2.1.5 Magnetization Transfer and Reaction Fluxes

One of the many advantages of NMR in cellular studies is that it can provide dynamic information about intracellular events, and give a measure of reaction fluxes catalyzed by enzymes, whether in the steady state or at equilibrium. The role of creatine kinase in skeletal muscle, heart, and brain has been debated for some years, and has been studied in these organs (in animal preparations) by magnetization transfer techniques.² In humans, creatine kinase fluxes have been measured in skeletal muscle, where it was shown that the PCr → ATP

flux decreases during exercise,³ and in the brain, where the activity was shown to be twice as high in gray as in white matter.⁴ These kinds of measurements as well as studies of ATP-synthase activities have not yet been explored further in human investigations, largely because of the time required for obtaining reliable data.

3 HUMAN DISEASE

In broad terms, human diseases that have been studied using MRS can be conveniently divided into four major categories (Sections 3.1–3.4 below).

3.1 Impaired Oxygen and Substrate Delivery

Oxygen delivery to tissues and organs depends on three factors: blood flow, hemoglobin concentration in the blood, and oxyhemoglobin dissociation characteristics. Alterations in any one of these parameters may impair oxidative phosphorylation, with a concomitant increase in anaerobic glycolysis leading to the production of lactic acid.

3.1.1 Muscle

Stenosis in limb arteries produces cramp and pain in patients, with intermittent claudication. ³¹P MRS has been used by several groups to investigate the metabolic consequences and severity of peripheral vascular disease. While at rest changes in metabolites and intracellular pH (pH_i) were observed in severe claudicants (the pH being significantly alkali), the most characteristic and specific changes were detected during exercise and during the following recovery phase. During exercise, PCr utilization and intracellular acidosis were enhanced, indicating a greater dependence on glycolytic mechanisms for energy production. The reduced rate

of PCr resynthesis is consistent with abnormal mitochondrial oxidation, and the slow pH recovery is indicative of substantially reduced blood flow and hence a decreased oxygen delivery (for a review, see Radda et al.³²).

The hyperbolic relationship between cytosolic [ADP] and rate of PCr resynthesis after exercise has been used to estimate the apparent maximum rate of oxidative ATP synthesis ($Q_{\max}$) in several human diseases in which mitochondrial oxidation may be impaired (see Table 1).²¹

Muscle responds to impaired oxidation by stimulating anaerobic ATP synthesis and/or by increasing [ADP], the stimulus to the mitochondrion. However, these responses interact: [ADP] depends on pH and [PCr], and lactic acid production tends to lower [ADP] (by lowering pH), while proton efflux has the opposite effect. Four patterns were identified:

- (d) in mitochondrial myopathy, apparent $Q_{\max}$ is reduced and [ADP] is appropriately increased, because increased proton efflux reduces the pH change in exercise despite increased lactic acid production;
- (e) in some conditions (e.g., cyanotic congenital heart disease), apparent $Q_{\max}$ is reduced, but there is no compensatory rise in [ADP], probably because anaerobic ATP synthesis during exercise is increased without increase in proton efflux;
- (f) in other conditions (e.g., myotonic dystrophy) [ADP] is increased during exercise, but apparent $Q_{\max}$ is normal, suggesting either an increase in proton efflux and/or decrease in anaerobic ATP synthesis during exercise;
- (g) there are also conditions (e.g., respiratory failure) where, despite impaired oxygen supply, both apparent $Q_{\max}$ and end-exercise [ADP] are normal.

Patients with heart failure might have been expected to have reduced muscle blood flow and, perhaps, reduced oxygen delivery due to arterial hypoxemia. Several groups, however, found no blood flow changes,³² but demonstrated reduced mitochondrial content and activity and increased glycolytic ca-

Table 1 Conditions with Probable or Possible Defects of Mitochondrial ATP Synthesis

Mechanism	Examples analyzed
Intrinsic mitochondrial defects	Mitochondrial myopathy Iron deficiency Cardiac failure Uremia
Impaired blood flow	Peripheral vascular disease
Reduced blood oxygen tension	Chronic respiratory failure Cyanotic congenital heart disease
Reduced blood oxygen content	Iron-deficient anemia Myelodysplastic anemia
Increased Hb oxygen affinity	Treatment with 12C79 ^a
Other conditions with increased [ADP] in exercise	Hypertension Duchenne dystrophy carriers Myotonic dystrophy

^a12C79 is an experimental 'left-shifter' drug, 5-(2-formyl-3-hydroxyphenoxy)pentanoic acid.

capacity in the muscles of such patients, the pattern of response falling largely in group (b) above.

3.1.2 Heart

The elucidation of the metabolic abnormalities in ischemic heart disease has been a major objective of MR spectroscopists for some time. Recently Weiss et al.²⁹ have demonstrated a decrease in the PCr-to-ATP ratio during hand grip exercise in patients with coronary heart disease and ischemia, reflecting a transient imbalance between O₂ supply and demand in the myocardium with compromised blood flow. Exercise testing in five of these patients after revascularization showed no changes in high-energy phosphates, as was also observed in normal subjects and in nine patients with nonischemic heart disease. The possibility that an exercise-linked spectroscopic test may markedly improve the recognition and evaluation of myocardial ischemia is certainly of great interest.

3.1.3 Brain

Several important clinical problems arising out of impaired O₂ delivery have been investigated by both ³¹P and ¹H MRS.

Perinatal asphyxia is the commonest cause of neurological handicap in full-term infants. Reynolds and colleagues³³ have studied infants with birth asphyxia from birth onwards. ³¹P NMR spectra from neonatal brain differ from those from the adult brain in that a large monoester peak, identified as phosphoethanolamine, is present and the ratios PCr/ATP are lower. These workers found that birth asphyxia caused significant changes in the ratio PCr/Pi, the magnitude of which was helpful in prognosis. These changes occurred early, and the ratios returned to normal within a few days.

Several ¹H MRS studies have reported that the *N*-acetylaspartate (NAA) signal in neurologically abnormal infants was lower than in normal controls (for a review, see Howe et al.³⁴).

Cerebrovascular disease and stroke are among the major causes of death in the adult population in the Western world. Numerous ¹H MRS studies in patients with stroke have suggested that NAA may be a marker for neuronal loss. Serial measurements of NAA following stroke demonstrated recovery of the NAA peak with neurological improvement.³⁴ Elevation of brain lactate during acute ischemia could be detected, but surprisingly lactate was also found within the infarcted area months after the event. The metabolic turnover of this lactate pool was demonstrated by the appearance of [¹³C]lactate, following infusion of [1-¹³C]glucose.³⁵ It has been suggested that brain macrophages, which begin to appear three days after infarction and gradually disappear over several months, could be a major source of elevated lactate signals that persists for months after stroke.³⁶ Levine et al. investigated early human focal ischemia with ³¹P MRS to characterize the temporal evolution and relationship of brain pH and phosphate energy metabolism.³⁷ Serial ischemic brain pH levels indicated a progression from early acidosis to subacute alkalosis. When acidosis was present, there was a significant elevation in the relative signal intensity of inorganic phosphate and significant reductions in signal intensities of ATP compared with those of control subjects. Ischemic brain pH values correlated directly with the relative signal intensity of PCr and the PCr index, and correlated inversely with the signal intensity of Pi. There was a

general lack of correlation between either ischemic brain pH or phosphate energy metabolism and the initial clinical stroke severity. The data suggested a link between high-energy phosphate metabolism and brain pH, especially during the period of ischemic brain acidosis, and the authors proposed that effective acute stroke therapy should be instituted during this period.

Subarachnoid hemorrhage may be complicated by cerebral ischemia, which, though reversible initially, can progress to an irreversible neurological deficit. ³¹P MRS studies of 10 patients on 30 occasions at various times after hemorrhage showed in some of the patients (*n* = 5) focal areas of intracellular acidosis (pH < 6.8), which in most cases returned towards normal.³⁸ The recovery of pH_i to normal paralleled an improvement in clinical conditions in each case. These areas of acidosis probably affect ischemia, which is potentially reversible. The MRS measurement provides an opportunity for assessing methods of treatment.

3.2 Genetic and Metabolic Diseases

MRS is particularly valuable in the study of metabolic diseases and genetic conditions.

3.2.1 Mitochondrial Disease

Abnormal mitochondria are increasingly recognized as being responsible for muscle and brain disorders. In primary mitochondrial diseases, there are mutations in the nuclear or mitochondrial genes necessary for the synthesis of the components of the electron transport chain. The functional bioenergetic consequences of these abnormalities can be studied by ³¹P MRS.³⁹ At rest, in both skeletal muscle and the brain, PCr/Pi and PCr/ATP are decreased, while the Pi/ATP ratio is often increased. This means that the phosphorylation potential, a measure of the available cellular energy, is decreased.

In skeletal muscle, oxidative ATP synthesis is impaired, and this often results in slow PCr resynthesis during recovery. As already pointed out (see Table 1), the reduction in mitochondrial *Q*_{max} is partly compensated for by an increase in free ADP during exercise and recovery, which stimulates the ATP synthesis rate. This arises from an apparent adaptation in the muscle to chronic mitochondrial insufficiency in which the rate of H⁺ removal from the cell by the Na⁺/H⁺ exchange mechanism is enhanced. This provides a protection to the cell against low pH that would arise out of excess lactate production, and also results in an increase in ADP through the creatine kinase equilibrium.

3.2.2 Diseases in Carbohydrate Metabolism

Defects of glycogenolysis and glycolysis are inborn errors of metabolism mainly of muscle or liver. As in the mitochondrial myopathies, the biochemical defects result in impaired production of ATP and in reduced (or absent) amounts of pyruvate for mitochondrial oxidation. Not only are the MRS findings in this group of disorders quite distinct from the oxidative disorders, but glycogenolytic defects are distinguishable from glycolytic defects.³²

Among several metabolic liver disorders, abnormal metabolism of fructose was studied in livers of patients with

hereditary fructose intolerance.⁴⁰ In this autosomal recessive disease, aldolase B activity is greatly reduced in liver, kidney, and small intestine. Homozygotes were easily detectable by MRS. Heterozygotes for this disorder cannot be identified by conventional tolerance tests, but in the MRS investigations they showed impaired tolerance to fructose compared with control subjects. In the heterozygotes, the rise in plasma urate after fructose (attributed to the activation of AMP deaminase by the low Pi concentration) correlated significantly with the decrease in liver Pi. The drop in liver Pi after fructose was very marked in those heterozygotes who also suffered from gout, suggesting that some patients suffering from gouty attacks might benefit from a low-fructose diet. Indeed, subsequent studies on a group of patients with a family history of gout show that in some families this resulted from being carriers of hereditary fructose intolerance, and a fructose-free diet improved their condition.⁴¹

¹H MRS has been used to detect specific signals in metabolic brain diseases. For example, high lactate concentrations were found in the brains of patients with Leigh's disease, and *N*-acetylaspartate was consistently increased in Canavan's disease, an inborn error of *N*-acetylaspartate metabolism.³⁴

3.2.3 Dystrophy

³¹P MRS studies of skeletal muscle bioenergetics in patients with muscular dystrophies have given new clues as to the functional consequences of the genetic lesion. For example, in patients with Duchenne (DMD) and Becker (BMD) muscular dystrophy, there is an increase in intracellular Pi and decrease in PCr. Intracellular pH was raised substantially in DMD, moderately in BMD, and slightly but significantly in carriers of the disease.^{2,42} Investigations on the mouse equivalent of DMD (the mdx mouse) have shown that the raised pH_i is linked to increased intracellular Na⁺ and Ca²⁺, suggesting that the absence of dystrophin in the muscle leads to a series of ionic abnormalities. Measurements of these biochemical parameters in vivo may provide a way of following the success of therapies such as might be achieved by gene replacement.

Dystrophin is also known to be absent in the brain (neuronal cells) of patients with DMD, and it is known that about 30% of such patients are mentally retarded. It is of interest, therefore, that abnormal Pi/PCr ratios are also observed in the brains of children with DMD and in the brain of the mdx mouse. Neuropsychological studies on such children have shown a relationship between full-scale IQ and the Pi/PCr in the brain.⁴³

3.3 Abnormal Control and Disease

The control and coordination of metabolic processes require an intricate network of input functions. Some of these have been emphasized in Section 2, while others include the role of specific ions, general ionic environment, potentials across intra- and extracellular membranes, concentrations of substrates, and hormonal input.

We may consider diseases arising out of a 'control lesion' as being primary intracellular or extracellular, i.e., systemic in origin.

3.3.1 Intracellular Control

There are several examples where MRS has led to the identification of defects that affect intracellular control. These include a patient with abnormal intracellular substrate transport in skeletal muscle (malate aspartate shuttle defect) and the recognition of a sarcoplasmic reticulum Ca²⁺-ATPase defect.³²

As already mentioned, perturbations in the ionic balance occur in Duchenne and Becker muscular dystrophy. There are other conditions where the rates of ion-exchange processes (Na⁺/H⁺ antiport/Na⁺/K⁺-ATPase) are significantly increased. For example, in essential hypertension, skeletal and heart muscle as well as vascular smooth muscle are affected in this way, as are other peripheral cells (white cells and erythrocytes). It is not known in this case to what extent these changes are secondary or whether they are related to the fundamental mechanism of the disease.²

3.3.2 Extracellular Control

The relationships between the extracellular environment (blood biochemistry) and intracellular processes is central to our understanding of physiological regulation.

3.3.2.1 Acid/Base Regulation In Vivo. This is an important physiological problem, with profound clinical implications. Intracellular pH regulation in individual organs and its dependence on the physiological acid/base balance can be examined very well by ³¹P MRS,⁴⁴ and many studies have been carried out on this problem in animal models and humans. Some illustrative examples are given below. Hood et al.⁴⁵ examined the effect of systemic pH on pH_i using ³¹P MRS by measuring lactic acid generation in the forearm muscle of a group of volunteers who performed exhaustive arm exercise with arterial blood flow occluded. On ingestion of NH₄Cl (acidosis), blood pH decreased to 7.30 from 7.39 (control), whereas muscle pH_i did not change. During alkalosis induced by NaHCO₃ ingestion, blood pH increased, while pH_i was again well controlled. Systemic acidosis inhibited and alkalosis stimulated lactic acid output (during exercise), which suggests that systemic pH regulates cellular acid production, protecting muscle pH at the expense of energy availability. In contrast, in severe respiratory acidosis produced by CO₂ breathing, muscle pH is significantly reduced.⁴⁵ The adult mammalian brain is protected from oscillations in arterial blood pH by a different mechanism, namely the blood-brain barrier, but it is not protected from changes in arterial partial pressure of CO₂ that have been shown to produce changes in the pH of cerebrospinal fluid. ³¹P MRS was used to measure intracellular pH in different parts of the human brain while the subject was breathing air, and during hypercapnea. The white matter responded with a greater decrease in pH_i than gray matter.⁴⁶ The response of liver to acidosis was examined in rats.⁴⁷ Varying severity of acidosis was induced by HCl infusion, NH₄Cl ingestion, or induction of experimental diabetic ketoacidosis. Whereas at the more severe degrees of systemic acidosis a marked decrease in hepatic pH_i was observed, there was little change in ketoacidosis. This explained why, in the latter condition, gluconeogenesis from lactate is not inhibited, despite evidence in vitro of inhibition of glyconeogenesis by systemic acidosis.

3.3.2.2 Cellular Inorganic Phosphate (Pi) Concentration and

Total Intracellular Phosphate. These are dependent on blood Pi homeostasis, which in turn is linked to renal Pi clearance and whole body phosphate incorporation and regulation in bones. The relationship between extracellular and intracellular concentrations of Pi was studied in the muscles and erythrocytes of patients with vitamin-D-resistant rickets and patients with Paget's disease of bone before and after they had been made hyperphosphatemic by treatment with the drug ethyldiene-1-hydroxy-1,1-biphosphonate. Even though the plasma Pi concentration in these patients spanned a fourfold range (0.5–2.0 mmol L⁻¹), the corresponding intramuscular Pi concentration increased by only 70%.³²

Patients in renal failure also have elevated blood phosphate, and again this is accompanied by a proportional but smaller increase in muscle Pi. In spite of this, in this condition, the resting phosphorylation potential remains unaltered, implying that cellular levels of ADP and ATP are adjusted to compensate for increase in Pi.

3.3.2.3 Hormonal Regulation of Metabolism. This has long been recognized, and MRS has been used in many investigations of patients with abnormal hormonal levels on hormonal control. The study of diabetes using ¹³C MRS has already been mentioned in Section 2.1.2. An extension of this work to insulin resistance is of some interest, since the latter may precede the diabetic condition.

Thyroid hormones affect metabolism in many tissues. Skeletal muscle metabolism has been examined in patients with both hypo- and hyperthyroid conditions.² The abnormalities found are totally reversible with treatment, and MRS is therefore particularly useful in the evaluation of the relationship between clinical symptoms (e.g., decreased exercise capacity in hypothyroidism) and the underlying metabolic abnormalities.

3.3.3 Tumor Biochemistry

Uncontrolled cellular growth and proliferation represent an extreme case of disease where normal molecular homeostasis is not observed. The study of tumor biochemistry by MRS represents a major area of clinical research, and advances in the field have been regularly reviewed since the 1980s and more recently examined in some detail.^{34,48}

In the majority of studies, ³¹P or ¹H MRS have been used but there are reports using ¹³C, ¹⁹F, and ²³Na as the nuclei of interest. Several specific developments have arisen out of the ³¹P MRS measurements.

1. The fact that the majority of human tumors were shown to have alkaline intracellular pH values—and not acidic as was expected—focused attention on the role of ionic control in relation to cellular proliferation.
2. The observation that many tumors had prominent signals in the phosphomonoester (PME) region, which were mostly associated with increased phosphoethanolamine and phosphocholine, brought into the forefront research on phospholipid metabolism in tumors. While it is still not known whether such changes are the result of alterations in the biosynthetic pathways or are associated with phospholipid degeneration and cellular signaling, the possibility that they can be used as an index of cellular proliferation rates has generated much interest.
3. Some researchers hoped that the bioenergetic status of the tumour as reflected in the ³¹P MR spectrum might be characteristic of tumor types. Others argued³² that such

measures of the metabolic state are more likely to provide an indication of the physiological state of a particular tumor in its specific location. The latter property could then be used to guide the choice of therapies that would utilize the state of oxygenation and activity of a given tumor at a defined stage of its development.

4. There is considerable evidence that response to therapy, particularly chemotherapy, might well be measurable by quantification of the phospholipid components.⁴⁸

Recently, there has been a rapid expansion in the use of ¹H MRS in clinical investigations of tumors.³⁴ Given that in most ¹H MRS experiments, only four peaks are measured, namely those assigned to *N*-acetylaspartate, total creatine, choline-containing molecules, and lactate, much emphasis has been placed on empirical correlations with other measurements (histology, PET, etc.) or on pattern recognition methods.³⁴ It is perceived that multicenter clinical trials might clarify the applicability of such approaches to the grading and possible diagnosis of human tumors.

3.4 Disease and Foreign Invasion

Biochemical changes associated with the administration of toxic substances, viral infections, inflammation, and autoimmune disorders are readily observed by MRS. Alcoholic liver disease, the hepatic consequences of paracetamol poisoning, and viral hepatitis are just some of the conditions that have been studied by ³¹P MRS.⁴⁹ Both the extent of damage and the liver regeneration process can be assessed from the MR measurements.

Acute liver failure can result in hepatic encephalopathy, possibly through the action of toxic substances like ammonia, mercaptans, and amino acids. Several ¹H MRS studies demonstrated an elevation of glutamine levels and the parallel decrease in brain myoinositol.^{34,50} Liver transplantation completely reversed the ¹H MRS changes. Other forms of treatment (e.g., by neomycin or lactulose) were also examined by Kreis et al.⁵⁰

4 CONCLUSIONS AND FUTURE PROSPECTS

This article has been written from the point of view of the author with emphasis on the biochemical aspects of human MRS. There can be no doubt that we have already learned a great deal from MRS about biochemical aspects of human diseases and control and fluxes in normal situations. The method is thus established as a truly new approach in clinical research. In some areas, such as muscle investigations and possibly the empirical uses of brain ¹H spectroscopy, it could be considered as part of clinical examination aimed at evaluation of the nature and severity of the disease. As the capability of obtaining spectra in a relatively routine manner becomes available on standard diagnostic imaging instruments, such examinations will become more common, though probably restricted to specialist centers. The author's bias remains, however, that, being a quantitative biochemical technique, the strength of MRS will remain in bringing new understanding about disease mechanisms. Once such understanding is derived from careful and focused studies

on specific conditions, we should attempt to devise simpler, cheaper, and generally more readily available tests, probably with a less precise information content, that can be adopted in daily clinical use.

1 INTRODUCTION

Since the 1960s, endoscopy has revolutionized the diagnosis and treatment of both upper and lower gastrointestinal (GI) disease and has become the gold standard in management. However, detection of disease is limited to visualization of the surface mucosa. The extent of invasion beneath the surface may be shown with biopsy, but lesions with no superficial component or those with infiltration remote from the biopsy site may be missed.¹ Ultrasound probes have been used in conjunction with endoscopy to address this problem, and transducers that can be passed down flexible gastroscopes² or bronchoscopes³ have been used in order to locate lesions and demonstrate their vascularity. However, low soft-tissue contrast limits the application of this technique.

MRI provides a valuable method for visualizing soft tissue; however, with conventional external whole-body or phased array receiver coils, image resolution of small areas of interest is generally low. Dedicated surface receiver coils can greatly improve image resolution of adjacent structures, and intracavitary coils have been used in the rectum and vagina for imaging the adjacent prostate and cervix.^{4,5} It is possible to use coils of this type in conjunction with a nonferromagnetic endoscope for MRI of lesions of the upper and lower GI tract.

2 MR-COMPATIBLE ENDOSCOPE DESIGN

Ferromagnetic materials are normally used in the construction of endoscopes. These not only produce an unacceptable degree of artefact but may be subject to movement forces when placed within the magnetic field. It is now possible to produce endoscopes from MR-compatible components. We have developed a MR-compatible gastroscope and colonoscope that contains no ferromagnetic materials (Endoscan Ltd, Burgess Hill, UK). The general handling attributes are similar to those of conventional instruments. An alloy of chrome is used as a substitute for the normal stainless steel guide wires. The conventional steel shroud, which provides integral strength, is replaced by copper braid. Each of the substitute materials is tested to ensure there is no significant MR artefact. The whole

assembly is encased in a heat-shrink sleeve that seals the instrument in an acceptable fashion.

The tip of the instrument is associated with the MR receiver coil and must be modified accordingly. In early versions of the endoscope, the coil was separated from the endoscope but used in conjunction with it. The coil could, therefore, be advanced away from the tip itself so that artefacts associated with components in the tip were not critical. The tip endpiece in this instrument is configured from an amalgam for the viewing lens, irrigation, and biopsy channels. Although polymers would be preferable, forming an impervious seal to the optics proved impossible and alloys of gold-plated copper were used instead. A newer version of the endoscope uses a coil design integral to the tip itself, which means that the tip must be artefact free and the tip design has to be appropriately modified to accommodate the coil circuitry.

The finished instrument incorporates conventional steering controls, an eyepiece, a light guide with an illumination source (Olympus CLE-3 with 150 W dichroic bulb), and a biopsy channel 2.8 mm in internal diameter (Figure 1). The length of the upper GI endoscope from eyepiece to tip is 1 m with a diameter of 12.5 mm, which equals that of a therapeutic gastroscope. The colonoscope is 1.7 m in length and 14 mm in diameter.

3 RECEIVER COIL DESIGN

The simplest design uses a solid coil that is separate from the endoscope itself but can be used in conjunction with it. The outer diameter of a rigid coil cannot be larger than that of the endoscope itself. Such a coil may be advanced some distance from the endoscopic viewing lens or pulled back up to it. It is maintained in the latter position during intubation of the pharynx. Advantages of its rigidity are not only ease of maintenance but also that it does not require tuning on every occasion. We have used a single turn saddle geometry receiver coil 25 mm in length and 10 mm in diameter wound on an acetyl homopolymer (Delrin) former. The conductor is of 18 swg varnish insulated copper and the on-board electronics contain no ferro- or paramagnetic materials. The receiver coil is connected to the external electronics by a specially constructed 50 ohm coaxial cable 2.1 mm in external diameter in a low-friction polytetrafluoroethylene (PTFE) jacket purpose built with MR-compatible components. The cable is accommodated within the biopsy channel of the endoscope.

The addition of an immobilization device to the coil, such as an inflatable balloon or suction cup, would greatly improve image quality. Inflatable balloon devices are currently in use with gastroscopic² and bronchoscopic³ transducers. However, inflatable designs require individual tuning and matching and are subject to distortion while the endoscope is being maneuvered.

Using the receiver coil separately from the tip itself has several disadvantages: it reduces maneuverability of the instrument, compromises optical field-of-view, and decreases suction (because its cable is fed through the biopsy channel). The incorporation of the receiver coil into the wall of the endoscope itself improves maneuverability and optical viewing. However, it is more challenging to construct and has important implications for housing and repair to the electronics. In particular,

Figure 1 MR-compatible endoscope and receiver coil (arrow). The appearance and handling of the endoscope are identical to a standard instrument. The receiver coil is the same diameter as the endoscope itself

immersion of the electronics during sterilization of the endoscope must be considered. In addition, the tip of the endoscope must be completely MR compatible in order to avoid unacceptable artefact on the images.

In our design, the coil incorporates an electronic switch that renders the coil electrically invisible during the transmit phase of the MR sequence. Computer controlled switching of rf is used to achieve this. Diodes are selected for their optimal rf switching characteristics while avoiding the ferromagnetic materials that are routinely found in conventional diodes. The small inductors used to form part of the rf switch have minimal detrimental effect on coil performance. A further circuit is provided to transform the impedance of the coil to match that of the transmission cable, thereby minimizing signal degradation within the cable. The capacitors used for both coil tuning and impedance transformation are selected for their high quality factor (Q), while avoiding the ferromagnetic nickel barrier terminations that are often preferred for capacitors in a mass-production environment. The board required to accommodate the additional coil control circuitry is typically 11.5 mm×10 mm and is placed immediately behind the coil.

The signal-to-noise ratio (SNR) figures for coil performance are often misleading. When compared with the standard pelvic phased array coil, the gastroscope coil performs significantly better at distances up to 2 cm from the coil surface. A clinically acceptable field-of-view for diagnostic purposes is obtained up to 2.5 cm from the coil surface. However, coil orientation relative to the fixed magnetic flux density field, B_0 , also has a significant effect on the local field-of-view. For a single coil, the regions in which the flux is parallel to B_0 pro-

duce no useful signal. Employing two or more coils each with a different orientation such that the blind spot of one is compensated for by the other may overcome this problem. Such coil arrays are crucial in imaging a tortuous structure such as the gut, where coil orientation is extremely variable.

4 SCANNER DESIGN

Modern short-bore magnet designs can be usefully adapted to perform MR endoscopy. Our experience has been with a short-bore design Picker Asset, where the distance from the magnet face to center is 60 cm and an operator can reach at arm's length into the center of the bore (Figure 2). Traditional MR scanner designs in which the patient is at a distance down the long magnet bore do not provide sufficient patient access and are unsuitable. The newer 'interventional' MR scanners (C-arm, double doughnut) specifically address the issues of patient accessibility, and their open-plan features are designed to cater for endoscopic procedures.

4.1 Pulse Sequences

Imaging strategies for use with the gastroscope receiver coil seek a balance between two major considerations. On the one hand the coil gives a large gain in sensitivity over a limited region that can be exploited to reduce patient scan times as well as to provide high-resolution images of immediately adjacent tissue. In particular, image wrap around is not an issue

Figure 2 MR endoscopic procedure being performed

when choosing small fields-of-view. On the other hand, it is important to avoid image degradation associated with motion. The exact sources of motion artefact depend on the positioning of the coil. Major contributions arise from the pulsatile motion of the heart and great vessels in the thorax and from respiratory motion, as well as from patient movement if scan times are too long. If no immobilization is provided for the receiver coil, the sensitivity profile is such that smearing of the very high signal from regions immediately adjacent to the coil occurs and can swamp signal from regions of interest a few centimeters from the coil.

There are many well-known strategies for dealing with motion artefact in MR imaging. In the upper GI tract, cardiac gating is useful. Typically a standard gated spin echo sequence will have a repetition time (TR) of 700–800 ms, so T_1 -weighted images, which provide useful anatomic landmarks, may be obtained. These sequences do not have a high gradient demand; consequently, with normal imaging gradients (10 mT m⁻¹ with a rise time of 1 ms), 3 mm slice thicknesses and 10 cm fields-of-view can be easily achieved. A small reduction in the achievable resolution and the number of slices that can be scanned (although still more than enough to cover the extent of

the coil) allows the use of gated fast-spin echo sequences, which significantly reduce the scan times. With longer pseudo-echo times, these sequences give more T_2 -weighted images.

Although gating greatly improves image quality, images collected in this way are still subject to extensive motion artefact. In these sedated patient examinations, breath-hold techniques are impractical while the requirement for high resolution means that single-shot techniques that have proved useful for body imaging, such as HASTE (half-Fourier acquisition single-shot turbo spin echo),⁶ require gradient performances well above those that are generally available. Single-slice, fast-scanning techniques may be used to further reduce artefact by 'freezing' motion. An alternative technique is to use gated fast gradient echo sequences with segmented k -space acquisition.^{7,8} At a TR of 15 ms, 32 lines or more of data can be collected per R–R interval and scan times of a few seconds are possible. Collection of the full image data can be divided over a few heartbeats. Optimization of the SNR depends on further refinements of the sequences, such as varying the flip angle through each cycle of data acquisition.⁹ Preparation pulses can be used before the data collection in each cardiac cycle in order to achieve the required image contrast. In combination with this, centrally ordered phase encoding seeks to collect views from the center of k -space early in each cycle of data collection.

In the colon, cardiac motion is not an issue; however residual bowel air reduces contact between the receiver coil and the bowel wall and facilitates movement of the coil within a distended lumen. Modified gradient optimized gradient echo sequences with a TR of 8–15 ms and TE of 3.7–6.1 ms can achieve a 1–25 s acquisition. In addition, versions of this sequence may be used with an inversion prepulse of 300–700 ms to maximize contrast between bowel wall layers.

Finally navigator echoes for line-by-line quantification of motion, together with postcorrection or phase encode re-ordering techniques, have been used in, for instance, cardiac imaging.^{10,11} For the application here, the limited field-of-view of the imaging coil means that navigator echoes are impractical. We have investigated exploiting similar techniques by adding an additional small receiver coil (internal diameter ~3 mm) within the tip of the endoscope, attached to a separate receiver channel and containing a small MR-visible fiducial marker (~1 mm diameter).¹² Motion of the endoscope tip can then be monitored by application of four gradient projections,¹³ acquired in 60 ms, before each line of data acquisition, from which the current position of the fiducial can be measured. In situations where fast scan times are not necessary for patient tolerance, this method allows full exploitation of the coil sensitivity for high-resolution imaging within the gradient performance of clinical scanners, as well as permitting the full range of diagnostic image contrast.

5 EX VIVO IMAGING

From inner to outer, four layers are seen in normal bowel (Figure 3). First, a layer of high signal intensity on both T_1 and T_2 -weighted images that represents the mucosa. Second, there is a layer of low signal intensity on T_1 -weighted imaging that represents the muscularis mucosa. This layer is intermediate in signal intensity on T_2 -weighted imaging and, therefore, indistinguishable from the adjacent outer layer. Third, a layer of

Figure 3 The normal colon ex vivo showing normal colonic layers. (a) Transverse spin echo T_1 -weighted image [repetition time (TR) 355 ms; echo time (TE) 20 ms]; (b) T_2 -weighted image (TR 2500 ms; TE 80 ms); (c) histologic section. The innermost ring of high signal intensity represents mucosal epithelium (arrowhead). The next thin layer of low signal intensity represents the muscularis mucosa (short arrow). The submucosa is seen as a band of high signal intensity in (a) and as an inner ring of intermediate signal intensity and an outer ring of low signal intensity in (b) (curved arrow). The muscularis propria is a thick band of low signal intensity in both (a) and (b) (long arrows). This correlates with the appearance on histologic section

high signal intensity on T_1 -weighted imaging is seen that has two counterparts on the T_2 -weighted images: an inner layer of intermediate signal intensity and an outer rim of lower signal intensity. These correspond to the submucosa. Finally, a homogeneous thick outer layer has low signal intensity on both T_1 - and T_2 -weighted imaging; this represents the muscularis propria.

6 IN VIVO STUDIES

6.1 Upper Gastrointestinal Tract

The procedure initially follows standard endoscopy practices. Following local anesthesia to the back of the pharynx, the patient's esophagus is intubated with the coil in advance of the tip of the endoscope. After visual inspection of the upper GI tract, the coil is placed adjacent to a lesion or region of interest under direct vision and the patient positioned with the region to be imaged in the center of the magnetic field.¹⁴

Use of a short-bore scanner (0.5 T, 60 cm from magnet face to center) allows access to the patient's mouth. Imaging strategies described in Section 4 are then used to study normal

anatomy (Figure 4), the extent of tumors (Figure 5), varices not detectable on visual inspection (Figure 6), and post-surgical appearances at the gastroesophageal junction.

6.2 Lower Gastrointestinal Tract

Patient preparation is identical to that used for a standard colonoscopy. During visual inspection of the colon, note is taken of areas where imaging may be of interest. On completion of inspection, the receiver coil is placed adjacent to these areas and images obtained. As in the ex vivo studies, three layers of bowel wall can be identified: mucosa, submucosa, and muscularis propria (Figure 7).

7 SAFETY ISSUES

7.1 Technical Factors

An alternating magnetic field gives rise to an electric field in a plane normal to the magnetic field. This statement of Faraday's law may be made more concisely as

Figure 4 The normal mid-esophagus. Spin echo T_1 -weighted transverse image (repetition time 660 ms; echo time 20 ms) showing normal esophagus (arrowhead), ascending and descending aorta (open arrows), and azygos vein (short arrow)

Figure 5 Carcinoma of the esophagus. Spin echo T_1 -weighted transverse image (repetition time 660 ms; echo time 20 ms) through the mid-esophagus showing a large mass of intermediate signal intensity in the mediastinum (arrowheads) surrounding the esophagus. A pulmonary vessel is seen passing through it (arrow)

Figure 6 Gastric varices. Electrocardiograph-gated spin echo T_1 -weighted transverse image (repetition time 660 ms; echo time 20 ms) at the level of the gastric fundus (open arrow) and coeliac axis (arrowhead). Numerous signal voids (arrows) at the splenic hilum represent recurrence of varices in the left gastric territory

Figure 7 Normal colon. In vivo spin echo T_1 -weighted transverse image (repetition time 660 ms; echo time 20 ms) through the sigmoid colon showing a trilaminar wall structure of mucosa (intermediate signal intensity; short arrow), submucosa (high signal intensity; curved arrow), and muscularis propria (low signal intensity; long arrow)

$$\oint \mathbf{E} d\mathbf{l} = \frac{-d}{dt} \int \mathbf{B} d\mathbf{A}$$

where $\mathbf{E}$ is the induced electric field strength along a path of length $d\mathbf{l}$, t is time, and $\mathbf{B}$ is the inducing magnetic flux density over an area $d\mathbf{A}$, all variables being vector qualities.

If we take the relatively simple case of a closed circuit path of radius r in free space in a plane normal to the magnetic flux, then $\oint \mathbf{E} d\mathbf{l} = E \cdot 2\pi r$. The corresponding rate of flux change is:

$$- \int \frac{d\mathbf{B}}{dt} d\mathbf{A}$$

which will have magnitude

$$\left| \frac{d\mathbf{B}}{dt} \right| \pi r^2.$$

Then

$$E \cdot 2\pi r = \frac{d\mathbf{B}}{dt} \pi r^2$$

and

$$E = \frac{dB}{dt} \frac{r}{2}$$

Consequently, the induced electric field increases linearly with the enclosed loop radius.

If part of this circular path is replaced by a conducting medium, a copper wire for example, the resulting electric field within the wire will be zero and the electric field around this loop will be concentrated into the lower conductivity portion of the loop outside the wire. Since, for a given diameter, the total loop electromotive force ($E \cdot 2\pi r$) is fixed, increasing the length of the wire portion of the loop to create a smaller gap will increase the electric field in the gap proportionately. Should this gap be now filled with a nonmetallic medium capable of supporting electric currents (e.g., human tissue), this relatively high electric field could give rise to currents sufficiently high to produce significant tissue heating and a potential safety hazard.

Such a situation can exist within a MR scanner if suitable precautions are not taken. The B_1 magnetic field, alternating at the Larmor frequency, typically irradiates the whole body. Under normal operating conditions, the induced electric fields and their associated currents are small enough that the resultant tissue heating is well within safety guidelines. However, the introduction of a conductor, for example an electrocardiograph lead positioned so as to form a large loop, can result in a large electric field between the ends of the loop. If this high-field region is adjacent to the body surface, the local electric current can produce tissue heating that far exceeds the safety guidelines, resulting, in extreme cases, in localized tissue burning. This conducting-loop problem could equally apply to a colonoscope, for example as it performs loops within the abdomen. This hazard is minimized by providing a sufficiently thick layer of insulating material of high dielectric strength between conductive material within the colonoscope and the external tissue, so ensuring that electric fields are confined largely within these layers and that their levels are kept within reasonable limits.

The coil is coated in an epoxy-based adhesive commonly used in medical devices. It is biologically inert and nontoxic, meeting US pharmacopeia biocompatibility standards, thus avoiding allergic reactions and long-term toxic effects. In addition, it is chemical and water resistant, which allows sterilization of the coil by soaking it in a solution of glutaraldehyde.

7.2 Clinical Factors

Upper GI endoscopy carries a significant morbidity and mortality.¹⁵ In a large prospective audit across 36 hospitals to include over 14 000 examinations, the death rate was 1 in 2000 and the morbidity rate 1 in 200; cardiorespiratory problems were most prominent and there was a strong relationship between the lack of monitoring and the use of high-dose benzodiazepines and adverse outcomes. A lack of recovery area and poor staffing exacerbates this problem. No complications have been experienced in our unit so far, but as the procedure is considerably longer than a standard upper GI endoscopy and often requires an additional dose of sedative, an

increase in the morbidity and mortality must be anticipated. Also although the patient is accessible, this is less than achieved in a standard procedure and all monitoring requires increased vigilance. Continuous oxygen and close observation of the sedated patient during the entire period of imaging must be maintained.

Performing endoscopy in the MR environment, therefore, requires additional considerations. The MR suite must be equipped with full resuscitation facilities nearby. This includes oxygen available to the patient in the scanner and a MR-compatible trolley to transfer a patient in an emergency to a space outside the scanner room where normal resuscitation procedure may be carried out. Finally, all staff must be trained in metal safety and in resuscitation practice peculiar to the MR environment.

8 FUTURE APPLICATIONS

MR endoscopy will provide a useful means of staging neoplastic masses in the upper and lower GI tract. It may also be used as a way of monitoring or guiding therapeutic interventions administered endoscopically. For example, injection or banding esophageal varices may benefit from being performed with simultaneous cross-sectional images so that the completeness and efficacy of the procedure can be monitored in realtime. Laser treatments for the palliative recanalization of esophageal carcinoma may also be monitored in this way, thus reducing the risks of perforation or inadequate treatment and optimizing treatment outcome.

9 CONCLUDING REMARKS

MR imaging using a surface coil placed within the GI tract during an endoscopic procedure enables visualization of mural and extramural lesion extension and may provide a useful adjunct to diagnostic upper and lower GI endoscopy. Formal evaluation of this technique and comparison with ultrasound, computed tomography, and surgical findings is warranted.

1 INTRODUCTION

The excellent anatomical detail and high level of soft tissue contrast provided by magnetic resonance imaging (MRI) are potentially of enormous value in guiding both diagnostic and therapeutic procedures. However, the use of MRI has been limited because of the poor access to the patient provided by most scanners and the practical difficulties of working within a magnetic field. Both these problems are now being addressed. Newer more open-plan magnet configurations provide greatly improved access to the patient, and manufacturers are now producing a wide range of MR-compatible equipment.

The indications for MR-guided diagnostic procedures include lesions visualized only with MRI, e.g. focal lesions in the breast where MR-guided biopsy may be carried out using MR-compatible needles. The technical aspects of such procedures may also be simpler under MR guidance when particular access routes are preferred because of the oblique planes and 3D acquisition facility offered by MRI. In addition, MR-guided diagnostic procedures may be performed via endoscopes and facilitated by the use of specially designed insertable coils. These dedicated surface coils inserted through body orifices or into blood vessels and placed adjacent to localized areas of interest, e.g. cervix, prostate, oesophagus, and inner ear, provide remarkably high resolution images.

MR-guided therapeutic procedures are largely performed through flexible fiber-optic endoscopes, and may embrace a wide clinical spectrum of applications including treatment of very common conditions such as benign prostatic hypertrophy and prolapsed intervertebral disks.

2 MR-GUIDED DIAGNOSTIC PROCEDURES

2.1 Breast Biopsy

Over a decade has elapsed since the first clinical trials predicted an important role for MRI in breast cancer diagnosis.¹⁻³ Use of gadopentate dimeglumine as a contrast agent in the

1980s showed that malignant breast tumors enhanced reliably and predictably,⁴⁻⁶ and thus lack of enhancement excludes malignancy. However, other lesions such as atypical hyperplasia and areas of fibrocystic change also enhance, so that the specificity of MRI for malignancy is low.⁷ More detailed studies demonstrated that cancers enhanced early, and were best discriminated from benign lesions in the first 2 min after injection of contrast agent.⁵ The rise time for the enhancement of benign lesions, such as sclerosing adenosis and fibroadenomas, is generally slower than for neoplastic lesions,⁷ but there is overlap in individual cases, which makes it difficult to exclude a definitive diagnosis of malignancy with the necessary high level of certainty.

These difficulties in interpretation are compounded following treatment with surgery and/or radiation therapy. Post-treatment changes mimic malignancy clinically, mammographically, and on ultrasound.⁸⁻¹¹ Mammographic evaluation of such breasts is frequently impaired by decreased compressibility, generalized or locally increased density, architectural distortion, skin thickening, mass-like areas of fibrosis or fat necrosis, and indeterminate microcalcification. Furthermore, different radiation protocols as well as individual differences in tissue response may affect the timing of this enhancement seen on MRI. As a result, histology is frequently necessary not only for the diagnosis of the primary lesion but also for the diagnosis of disease recurrence in treated patients.

MR-guided biopsy can therefore provide histological diagnosis of primary lesions not visible on mammography, secondary foci and nonspecific areas of contrast enhancement, and lesions visible in mammographically uninterpretable cases, e.g. dense and treated breasts. It provides a means for identifying multifocal disease where mastectomy rather than lumpectomy may be indicated. MRI may also be used for evaluating and biopsying focal clinical abnormalities during pregnancy when mammography and radiation exposure are undesirable.

2.1.1 Techniques

Several schemes for MR-guided breast biopsy have so far emerged. One method uses the patient in the prone position with the breast under gentle compression in a multicoil array. Following the diagnostic study the lesion is reimaged using an interventional device consisting of a perforated lateral plate incorporating a single coil and a medial plate incorporating two coils.¹² Intravenous gadolinium contrast agent is administered for lesion identification, and fiducials are used to calculate the coordinates of the entry site.

Stereotactic MR-compatible biopsy equipment is now becoming commercially available, and may be used to place needles with 1 mm accuracy. The first step is the acquisition of the 3D data set, which is equivalent to obtaining the scout views for stereotactic mammographic biopsy. The coordinates of the lesion are then calculated from the reconstructed images, and entered into the unit which aligns the gun and needle along the proper trajectory. In comparison with conventional stereotactic mammography, use of the 3D data set reduces the errors associated with estimation of tip position and makes it possible to visualize the lesion and the needle trajectory in three planes.

In patients who have had surgery and radiotherapy to the axilla, elevation of the arm is difficult and sometimes painful, making the prone position unacceptable. In these patients the

Figure 1 Breast biopsy device comprising baseplate with integral surface coil and (a) upper compression plate with holes for needle access and (b) shaped thermoplastic material. This is immobilized on three sides to the modified baseplate using Plexiglas blocks

breast may be immobilized in the lateral decubitus position. This provides the added advantage of an easy medial or lateral needle approach that automatically runs parallel to the chest wall. This is essential in the distorted scarred breast, where the lesion is often retracted toward the chest wall. Also, in the lateral decubitus position, good access is provided to lateral lesions of the uppermost breast and medial lesions of the lowermost breast. Our biopsy device consists of a rectangular receiver coil coupled to a mechanism for immobilization (Figure 1). The receiver coil is a 180×80 mm rectangle of copper foil. The coil is mounted at a distance of 2 mm from a double split radiofrequency screen to minimize electric field effects.¹³ The whole assembly is mounted 10 mm behind the breast support plate.

Immobilization is achieved by using two flat compression plates with one edge contoured to the chest wall. The lower plate incorporates the rectangular receiver coil mounted on its outer surface. The upper plate contains a 250×140 mm area of holes approximately 5 mm apart. The plates are connected by two posts: the position of the upper plate can be adjusted, and it is locked in place when breast compression is adequate (Figure 1(a)).

Adequate immobilization with a greater degree of comfort may be achieved using a nonshrinking thermoplastic that is commercially available for use as a radiation therapy mask (Figure 1(b)). It is a thermoplastic that is rendered deformable by heating in a water bath at $70\text{--}80^\circ\text{C}$ for 30–60 s. It can then be stretched and molded around the breast to be biopsied. Hardening occurs in 60 s, after which it forms a rigid exoskeleton. It is fixed to the baseplate on three sides and fastened around the chest wall using tapes. Two MR-visible scales provide the X- and Y-coordinates of the lesion to be biopsied, and the depth is calibrated from the images in a perpendicular plane using an electronic caliper.

Another approach is to use MRI guidance without having to perform the biopsy within the bore of the scanner. This can be achieved by using frameless stereotaxy with an ultrasonic localizer. It is based on a localizing tip with a handle onto which two ultrasound emitters are mounted (the ‘wand’). Ultrasound detectors on a board placed nearby can locate the position of the tip in three dimensions to an accuracy of 2 mm (Figure 2). A 3D data set is then acquired with the breast

immobilized, and the data are transferred to a workstation. MR-visible fiducials placed on the breast and imaged at the same time are then registered in relation to the images of the breast using the ‘wand’. The image of the lesion and the position of the biopsy needle mounted on the localizing ‘wand’ can be displayed simultaneously on the screen so that the entry point and the needle trajectory can be planned.

2.1.2 Needles

A variety of MR-compatible hollow needles suitable for fine-needle aspiration cytology of the breast are currently commercially available in 22G, 20G, and 18G diameters and in 5, 10, and 15 cm lengths. The tip designs include straight short bevels (Lufkin needle, E-Z-M, New York, U.S.A.; Chiba needle, William Cook, Europe), a serrated edge (Franseen needle, William Cook, Europe), and a spiral cutting edge (Tip Cut needle, William Cook, Europe). With the serrated or spiral bevel needles, a 360° quick rotation of the needle prior to withdrawal may yield small fragments of tissue for histology. However, fine-needle aspiration has a failure rate due to insufficient tissue as high as 37%, and reported false-negative rates as high as 31%.¹⁴ The technical failure rate is higher in the treated breast, where sampling from an enhancing scar can produce a very acellular aspirate. In this situation, a two-piece cutting-edge core needle is usually necessary.

Even with MR-compatible alloys a small susceptibility effect may be seen around the needle. This may arise from the metal itself or the air within. Seen in cross-section, this artifact appears as a triangular central signal void with bright edges (Figure 3). It varies with magnetic field strength, alloy, and diameter of needle. Operators should be familiar with the type and amount of artifacts produced by the needles they are using at their particular operating frequencies in order to avoid errors in locating the needle.

2.1.3 Image Localization and Marking of Lesions Prior to Surgery

Needle marking for localization of breast lesions based on imaging immediately prior to surgery was developed

Figure 2 Targeting a breast lesion using a 3D data set. The needle trajectory is projected in three planes in relation to the lesion and the surface entry point

to reduce the amount of tissue excised during biopsy.^{15–18} The original technique involved the freehand placement of a needle in the breast as a marker to guide the surgeon.¹⁵ Although needle localization is more accurate than the external localization alone, there are significant problems due to needle displacement before or during surgery. Localization wires with hooked ends have been developed to secure the tip of the marker wire in place within the breast,^{19–21} but with mammography these may become displaced because patient and breast movement may occur when altering the position of the compression plates in order to obtain an image in a perpendicular plane.

MRI not only provides 2D imaging in multiple planes without moving the patient, but a volume acquisition allows reconstruction in multiple planes. MR-compatible marker wires are now commercially available (Kopans wire, William Cook, Europe), and, using a technique similar to that for MR-guided breast biopsy, it is possible to place a hooked wire in a lesion and confirm its positioning using a 3D imaging data set. With faster scanning methods it will also be possible to use real-time guidance to advance and steer the wire into the center of the lesion.

2.2 Upper Gastrointestinal Endoscopy

Upper gastrointestinal endoscopy is limited to visualizing lesions on the surface mucosa, and though the extent of invasion beneath the surface may be shown with biopsy,

lesions with no surface component or those with infiltration remote from the biopsy site remain a problem in diagnosis. MRI provides a means of visualizing the full submucosal and intramural extent of a lesion deep to the surface, and thus complements existing techniques.

Endoscopes require detailed reengineering to be acceptable for use in an MR scanner. Because many of the component parts of a standard endoscope such as the steel tension steering wires have a detrimental effect on the uniformity of the static magnetic field (B_0), it is necessary to replace them with MR-compatible alloys. In other respects the appearance and function of such an instrument [Figure 4(a)] are identical to those of a standard endoscope.²²

A small coil positioned just ahead of the endoscope and inserted with it may be placed in the upper gastrointestinal tract adjacent to surface lesions or suspected sites of pathology. A coil 50 mm in length with a diameter identical to that of the endoscope is optimal for ease of insertion whilst retaining a useful field of view for imaging. We have developed such a coil which incorporates a hybrid circuit to satisfy tune and match as well as decoupling requirements [Figure 4(b)]. The cable to the coil is fed through the biopsy channel of the endoscope. The procedure is performed under sedation in the center of the magnetic field. This can easily be managed in an open-plan or even a short-bore magnet such as the Picker Asset (70 cm magnet face to center plane) whilst maintaining full monitoring with pulse oximetry and electrocardiography, as well as providing pharyngeal suction as necessary.

Figure 3 T_1 -weighted SE (660/20) (a) sagittal and (b) axial scans with an MR-compatible needle in situ during a biopsy procedure. The needle tip lies at the periphery of enhancing scar tissue (arrow)

Imaging in the esophagus with the coil in position necessitates the use of cardiac gating or fast imaging techniques to reduce motion artifacts from the heart and great vessels. High-resolution images of the esophagus and adjacent mediastinum (Figure 5) may be obtained.²² Initial experience with this technique is promising for visualizing intramural changes (for example, mural thickening may be seen at the level of a stricture in reflux esophagitis).

2.3 Insertable Coils

These have been developed for endovaginal use in order to image the cervix, for endorectal use to image the prostate, for

endoanal use to image the anal sphincter, and for use in the external auditory meatus to image the cochlea.

2.3.1 Cervix

In early cervical neoplasia, conventional MRI is of limited value in detecting invasion of the cervix when this is only of the order of a few millimeters.²³ There are also difficulties in demonstrating extension of disease into the urinary bladder,²⁴ as well as involvement of adjacent parametrial lymph nodes. Endorectal coils have therefore been used to increase the resolution of cervical images,²⁵ but while this helps to visualize the posterior lip of the cervix, the drop off of signal anteriorly makes demonstration of the anterior lip of the cervix and the fascial planes between the cervix and bladder difficult.

We have developed a solenoidal receiver coil mounted on an acetabular homopolymer (Delrin) former (internal diameter, 37 mm) for endovaginal placement around the uterine cervix which provides high-resolution images of this structure.²⁶ The coil is attached to a 20 cm tubular Delrin handle (Figure 6). Although designs with an angle of 45° between the coil and handle have been used, in most cases a design with no angle between the coil and handle suffices. A 10–15 cm field of view is optimal, as good parametrial detail is seen up to 6 cm from the center of the coil. With this technique (pixel size, 0.6 mm^2), details of the endocervical mucosa are easily distinguished, as well as the inner and outer zones of cervical stroma [Figure 7(a)]. The mucosa shows a smooth and regular outline in the nulliparous cervix and a more irregular and indented outline in the parous cervix. In addition, dilated glands filled with secretions are sometimes seen in the latter group. This detail is rarely provided by standard body coil or even phased-array coil images. The stromal zones are readily distinguished, and no obvious differences are seen in women taking the oral contraceptive pill or between the follicular and luteal phases of the menstrual cycle.

On administration of 0.1 mmol kg^{-1} of gadopentate dimeglumine, brisk mucosal enhancement is seen at 30 s, which peaks at about 120 s after injection. The inner and outer stroma enhance more slowly, with the outer zone showing more prominent enhancement, and zonal differentiation being maximal at about 90 s.²⁶

In Stage I carcinoma, use of an internal coil provides accurate delineation of neoplastic lesions [Figure 7(b)], including the precise position and extent of stromal invasion as well as of extension of the tumor into the parametrium, bladder base, rectum, and locoregional lymph nodes.²⁷

2.3.2 Endorectal Coil

Carcinoma of the prostate is the second leading cause of cancer death in males. For younger patients, surgical excision offers the best chance of survival. MRI using an endorectal coil helps distinguish whether the disease is confined to the capsule and is therefore suitable for treatment by radical prostatectomy.

The first prototype endorectal coil was developed in 1988, and a $3.5 \times 8 \text{ cm}$ inflatable version is now commercially available with a tune and match box (Medrad, Pittsburgh, USA). It provides a two- to fourfold increase in the signal-to-noise ratio, and allows thin slices (3.0 mm) and small fields of view (10 cm) to be used. It is flexible, and may be inserted with a minimum of discomfort. As the device requires inflation of

Figure 4 (a) MR compatible gastroscop. The internal receiver coil cable is passed through the biopsy channel. (b) Internal receiver coil with integral electronics for an endoscope. The diameter of the coil is the same as that of the endoscope

Figure 5 T_1 -weighted SE (600/20) transverse image through the midoesophagus of a normal volunteer showing the trachea (short arrow), aorta (long arrow), and signal void from a coil in the oesophagus (arrowhead)

Figure 6 Intravaginal coil with a clamp stand for immobilizing it in situ. The height, angle, and tilt can be adjusted at both universal joints (arrows)

a balloon in the rectum, potential contraindications to its use are radiation strictures, rectal fistulas, and obstructing rectal masses.

Maximal contrast between the central and peripheral zones of the prostate is obtained on the T_2 -weighted images, where the central zone appears of low signal intensity and the peripheral zone, which is more prominent posteriorly, is of intermediate signal intensity [see Figure 12(a)]. With increasing age the

central zone enlarges and may become adenomatous (benign prostatic hypertrophy). Nodular components within such an adenoma are often mucus-containing, and are seen as high signals on the T_2 -weighted scans (Figure 8).

Carcinomas tend to occur in the peripheral zone often adjacent to the capsule, and are usually seen as low signal intensity nodules. The use of fat suppression techniques either with an inversion recovery approach²⁸ or with chemical saturation using either frequency selective chemical saturation

Figure 7 T_2 -weighted SE (2500/80) transverse images obtained with a cervical coil in the normal nulliparous cervix show (a) a regular mucosal outline (small arrows) and a low signal intensity inner stromal zone (arrowheads). Nabothian follicles are clearly seen (long arrows). (b) In Stage I cancer the inner stromal zone is displaced by the central tumor (arrowheads)

or a three-point Dixon technique²⁹ has been reported to improve the detection of the capsular penetration. Experience with gadopentate dimeglumine in the preoperative assessment of carcinoma of the prostate has proved it to be of marginal use, with no improvement in the detection of malignant nodules over the T_2 -weighted images.³⁰

Use of an endorectal coil improves the overall staging efficacy of MR over body coil images.³¹ Minor extracapsular invasion may be identified as an irregular bulge or asymmetry of the neurovascular bundle due to retraction. Tumor infiltration of the normally fluid-filled seminal vesicles is seen as low signal intensity foci within them on the T_2 -weighted

Figure 8 T_2 -weighted SE (1000/130) transverse image through the mid-prostate in benign prostatic hypertrophy. The central zone of the gland is nodular and massively enlarged. Mucus-containing nodules with long T_2 components (arrow) are prominent

images.³² However, low-signal areas in the seminal vesicles may also result from calculi or adenomatous nodules of benign prostatic hypertrophy protruding posteriorly. Understaging of prostatic carcinoma despite the use of an endorectal coil is common, and may occur because sheets of infiltrating neoplastic cells grow around glandular structures without causing displacement or distortion. Moreover, microscopic extension into the walls of the seminal vesicles is frequent and often cannot be demonstrated even with the increased resolution afforded by the endorectal coil technique.

2.3.3 Anal Coil

Disruption of the function of the anal sphincter is a common and distressing problem in which preoperative imaging is of considerable value. At present, transrectal sonography is the 'gold standard' for this purpose, but differentiation of the muscle layers (particularly anteriorly in females) is not always possible.³³ MRI of the anal sphincter with a dedicated coil provides very high-resolution images of the muscle layers.

We have developed a coil consisting of a simple saddle geometry on a 9 mm diameter Delrin former.³⁴ The length of the coil is 50 mm, and it is designed to image the anal sphincter from the subcutaneous external component to the lower rectum. The coil is encased in an outer sheath, and molded in shape so that it is anatomically acceptable. It incorporates a hybrid circuit to satisfy tune and match as well as B_1 decoupling requirements. To reduce coil motion during imaging, we immobilize it in an external clamp which is mounted on a baseplate under the patient's thighs. Universal bossheads allow adjustment of the angle and tilt of the coil (Figure 9).

Good differentiation is obtained between the external sphincter, longitudinal muscle of the rectum, and the internal sphincter³⁴ (Figure 10). The internal sphincter is of high signal intensity on both T_1 - and T_2 -weighting, and enhances very briskly on administration of intravenous gadopentate dimeglumine.

2.3.4 Ear Coil

An 8×10 mm coil angled at 55° to mimic anatomically the plane of the tympanic membrane may be inserted under direct

Figure 9 Insertable anal coil with integral electronics for imaging the sphincter. The coil may be immobilized in a clamp stand during imaging

Figure 10 T_1 -weighted SE (720/20) transverse image through the normal anal sphincter showing the internal sphincter (arrowhead), the longitudinal muscle of the rectum (short arrow), and the external sphincter (long arrow)

vision into the external auditory meatus in order to obtain high-resolution images of the cochlea and semicircular canals (Figure 11).

Placement of such a coil is best performed with an operating microscope, and may also require local anesthesia of the tympanic membrane.

3 MR-GUIDED THERAPEUTIC PROCEDURES

3.1 Laser Thermotherapy Techniques

Tissue damage can be produced for therapeutic purposes using lasers. The extent depends on the distribution of the laser light, the optical properties of the target tissue and the wavelength of the light used. The most important effects are

Figure 11 T_2 -weighted SE (2500/80) coronal images through the petrous temporal bone in a cadaver specimen using a dedicated ear coil in the external auditory canal. High-resolution images of the cochlea (arrow) and semicircular canals (arrowhead) are obtained

thermal, as a result of the laser energy being dissipated in the target tissue as heat. The neodymium:yttrium aluminum garnet (Nd:YAG) laser with its near-infrared beam penetrates tissues for several millimeters, and may be transmitted via flexible optical fibers. These fibers can be passed down hollow needles into solid organs in order to carbonize tissue at low power (2–5 W),³⁵ or may be passed down endoscopes into hollow organs and be used at much higher powers (50–70 W) to recanalize them, e.g. in the esophagus, and urethra.³⁶ Such treatments achieve in situ necrosis of tissue, but the dose of laser energy is often empirical, and the depth of penetration and extent of tissue damage is frequently unknown. The use of MR to image tissue changes during the delivery of laser energy helps visualize the degree and extent of the changes, so that the dose of laser energy may be matched to the tissue response.

Previous animal studies have correlated laser-induced acute tissue damage with pathological findings.^{37–39} During application of laser energy to rabbit muscle with a direct contact fiber at 2000 J, three layers were seen with T_2 -weighted MR scans: a central cavity with a high signal rim corresponding to carbonized tissue, a broad low signal intensity layer corresponding to denatured tissue with a zone of coagulative necrosis, and a high signal zone corresponding to a layer of edema.³⁹ Similar therapy in patients with liver tumors using a diffusing fiber tip implanted directly in the lesion and 4320 J of laser energy demonstrated an area of hyperintensity on T_1 -weighted scans at 2 min.⁴⁰ This may have been due to the formation of methemoglobin in the heated tissue, as has been shown in vitro.⁴¹

The noncontact mode and a side-firing technique at 40–60 W may be used in hollow organs such as the prostate to achieve maximal coagulation and minimal evaporation of tissue.⁴² With this technique, improvement in symptoms may occur due to sloughing of tissue over a period of months. However, this may also cause obstructive and/or irritative symptoms for variable periods of time.^{43,44} The technique

was perfected on a canine prostate model,⁴³ which, unlike the human prostate, is very acinar and has little stroma.⁴⁵ It therefore undergoes more dramatic sloughing of tissue when laser coagulation is performed.

3.1.1 Laser Prostatectomy

Endoscopic laser ablation (ELAP) is challenging the position of transurethral prostatectomy (TURP) in the management of benign prostatic hyperplasia because it offers major advantages over TURP such as reduced blood loss and greatly reduced hospital stay.³⁶ However, unlike TURP, the subjective and objective benefits associated with ELAP are usually not apparent for several weeks after treatment, and the resulting cavitation in the prostate is much less. As a result there may be much less long-term benefit from the procedure.⁴⁶ MR-monitored ELAP provides a method of imaging during treatment, allowing the operator to match tissue changes to the size and shape of the prostate in order to improve the long-term clinical outcome.

The procedure may be performed in the MR suite under general or regional (spinal or epidural) anesthesia. After establishing anesthesia the patient is transferred to the scanning table, and preoperative images are obtained using an endorectal receiver coil. A suprapubic catheter is inserted to maintain adequate irrigation throughout the laser therapy. In a short-bore design magnet, the patient's head lies outside the magnet whilst imaging the pelvis, thus facilitating continuous anesthetic monitoring.⁴⁷

Using a Nd:YAG laser (Cardiolase 4000 Triamedyne Inc., USA) with a side-firing fiber (Bard, USA), a standard four-quadrant ablation of 40W in each quadrant for 90s (14 400J) in our group of patients produced a striking increase in glandular size (approximately 34%) on the immediate postoperative images.⁴⁷ This swelling was accompanied by a loss of the nodular architecture of the gland. An area of T_1 shortening was seen in some cases. On the T_2W scans, development of a periurethral band of low signal was seen in the immediate postoperative period [Figure 12(a) and (b)].

Figure 12 T_2 -weighted SE (2500/80) transverse images through the prostate (a) before, (b) immediately after, and (c) 3 months following laser prostatectomy. In addition to glandular swelling and loss of nodular architecture, in image (b) there is a high-signal central region immediately adjacent to the catheter and probably related to it. Outside of this area there is a diffuse low-signal region within the prostate (arrows). (c) At 3 months there is a well-demarcated low-signal ring (arrowheads) several millimeters from the urethra (open arrow), but no evidence of cavitation

Glandular swelling was markedly reduced 1 week later, and resolved 3 months postoperatively. At this time a well-demarcated low-signal ring was seen several millimeters away from the urethra [Figure 12(c)]. The appearance of the gland was otherwise unchanged from the preoperative appearance, and there was no significant reduction in prostatic size or evidence of periurethral cavity formation.

3.1.2 Laser Discectomy

It has been possible to place hollow needles within the nerve root foraminae using real-time MRI, and pass microendoscopes down these in order to visualize fragments of prolapsed disk material and the adjacent nerve root prior to laser discectomy under direct vision.⁴⁸

3.2 Cryoablation, Radiofrequency Ablation, and Focused Ultrasound

These modalities produce useful tissue ablation and have all been used to a limited extent under MR guidance.^{49–52} The equipment necessary is cumbersome, and not only must it be rendered MR compatible but it must be easy to manipulate if access to the patient is limited. The issue of radiofrequency shielding of such equipment whilst in use during scanning also requires consideration. Cryotherapy has the particular advantage of freezing the mobile protons and creating a 'black hole' effect in the treated area, thus sharply demarcating treated from normal tissue.⁵¹ Technical advances and the trend toward image-guided minimally invasive intervention are making these techniques more popular.

4 CONCLUSIONS

MRI offers unique advantages of good soft tissue contrast as well as multiplanar cross-sectional imaging. Its potential for monitoring and guiding radiological and surgical interventional procedures is now beginning to be expanded. It should enable many procedures to be optimized whilst reducing their complications, thus making minimally invasive therapy safer and more cost-effective.

MR-Guided Biopsy, Aspiration, and Cyst Drainage

Jonathan S. Lewin

University Hospitals of Cleveland and Case Western Reserve University, Cleveland, OH, USA

1 INTRODUCTION

As the practice of radiology has evolved since the late 1980s, there has been increasing emphasis on intervention. Recent trends in minimally invasive methods for diagnosis and treatments have created a burgeoning interest in the use of MRI for guidance of radiological procedures.

Historically, the relatively long imaging times and the difficulty in patient access resulting from closed-bore superconducting cylindrical system designs have combined to make MR an unlikely guidance modality for radiological procedures. More recently, many of these disadvantages have been overcome with the advent of system hardware and pulse sequence improvements that have allowed the development of rapid imaging on open systems. This chapter discusses the hardware and software improvements that have made interventional MRI a reality and the use of this technology for guidance of biopsy, aspirations, and cyst drainage.

2 IMAGING SYSTEM DEVELOPMENT

Recent advances in magnet and system design have accelerated progress in MR-guided intervention. Many different MR system configurations have been used to guide percutaneous procedures. Each of these systems has advantages and disadvantages, with a constant tradeoff between signal-to-noise ratio, (SNR) access to the patient, useable field of view, and expense.

The use of MRI for interventional procedure guidance includes its use by radiologists during manipulation of needles, electrodes, catheters, or laser fibers. This form of intervention requires a significant departure from conventional diagnostic concepts and traditional imaging systems.

The factors contributing to high image quality in diagnostic MR include system field strength and the homogeneity and stability of the static and gradient magnetic fields. These factors are best obtainable by decreasing the 'openness' of an imaging system. The optimal design of a magnet with regard to field homogeneity would be a complete sphere, without opening.¹ In contrast, the environment best suited to radiological intervention is one with maximum access to the patient, allowing complete freedom in interventional approach and maintaining close proximity of monitoring and therapeutic devices. These attributes are in direct opposition to those facilitating image quality.¹ The use of MRI for guidance of interventional pro-

cedures has required a compromise between these opposing forces; this balance has been achieved through a number of different concepts and solutions.

Some of the first interventional procedures under MRI guidance were performed on conventional cylindrical systems, simplifying imaging but significantly compromising the access to the patient that is necessary for performance of the procedure and monitoring of patient discomfort and safety. Biopsy and aspiration procedures have been and can be performed using these cylindrical superconducting systems, but the patient must be withdrawn from the magnet in order to reposition the needle between scans.² This results in relatively long procedure times and contributed to the sparse use of MRI for biopsy and aspiration during the late 1980s. In particular, when the lesion in question was visible and accessible for biopsy by computed tomography (CT) or ultrasound, these more conventional methods for procedure guidance were clearly better suited modalities.

These disadvantages were overcome, in part, through the access to the patient provided by permanent or resistive 'open' magnet imaging systems.³⁻⁶ Unfortunately, the open low-field imaging systems available in the late 1980s often required significant imaging time to obtain a sufficiently high SNR to allow needle insertion under MRI guidance. However, the access to the patient provided by these systems led to an increased number of reports of its use, primarily for biopsy in the head and neck region.⁷⁻⁹

Since then, many magnet, gradient, and receiver chain design improvements have occurred and have led to a number of approaches for interventional imaging. A brief description of the most commonly used current designs for intervention follows. Each system has benefits and limitations for interventional procedure guidance, as each has chosen a different balance between the spatial constraints necessary for high-quality imaging and the freedom necessary for surgical or radiological intervention.

2.1 Cylindrical Superconducting Systems

From an image quality viewpoint, cylindrical superconducting systems enjoy many significant advantages relative to static magnetic field strength and homogeneity, and the adoption of this system design as the standard for image quality in the diagnostic arena is not a chance occurrence. The limited patient access for procedure performance and direct visual observation is a compromise that still allows certain procedures.

One more recent approach to the use of cylindrical superconducting systems for interventional procedures has been the siting of a superconducting system in an interventional or surgical environment. With the rapid fall-off of the static magnetic field achieved by actively shielded magnet designs, it is possible to site a superconducting system in near proximity to a surgical work space. This design has been adopted in a system constructed by Philips Medical systems (Eindhoven, the Netherlands) in which a procedure suite including a fluoroscopy system has been constructed just outside of the fringe field of a superconducting short-bore 1.5 T imaging system. Fluoroscopic or angiographic procedures can be performed in a conventional manner. However, when desired, intermittent images can be obtained by sliding the patient into the cylindrical imaging system. The imaging system allows all of the standard capabilities of a high-field system, including functional imaging, with high

image quality. Although there are very few compromises to either the fluoroscopic or MRI portions of this environment, this configuration does not allow interactive MR guidance of the intervention, as access to the patient is markedly limited. Therefore, needle placement under MR guidance must still be performed in an 'in and out' manner, which can be time consuming for difficult needle placements. Once a needle is placed, the access to fluoroscopy can greatly facilitate guide-wire and catheter placement during drainage procedures.

The use of cylindrical magnets has also been successfully applied for guidance of stereotactic biopsy for breast lesions.¹⁰ This type of stereotactic procedure lends itself well to the immobilized breast but is less applicable to most other areas in which motion is more of an issue.

2.2 'Double Donut' Configuration

A novel approach to obtaining access to a patient in a cylindrical system is exemplified in the 'double donut' configuration of the General Electric Medical Systems Signa SP system (Milwaukee, WI), designed specifically for interventional applications.¹¹⁻¹³ This design has taken the central segment out of a cylindrical system, allowing access to the patient from the sides and top at the isocenter of the imaging system. This product design has been directed toward siting in a surgical environment and allows enough room in the gaps between the halves (54 cm) for two physicians or nurses, one on either side of the patient.¹ This system provides a marked improvement in access to the patient relative to a closed-bore cylindrical system, although the technology is expensive. This concept represents the first system designed and constructed specifically for interventional guidance. This magnet design has been used both to guide and to monitor a large number of surgical procedures, in addition to an early published series of biopsies and aspirations.^{12,14,15} However, the marked improvement in access to the patient is achieved at the expense of a decrease in field strength at the imaging isocenter (0.5 T imaging field strength) compared with the field generated by each individual superconducting half, and it compromises magnetic field homogeneity.¹ The unobstructed side and vertical access to the patient also complicates the engineering of the radiofrequency coil, requiring a local transmit-receive coil with a somewhat limited field of view.

2.3 Biplanar Magnet Designs

Another approach that has found widespread application for diagnostic MRI in the burgeoning 'open MRI' market has been the use of a biplanar magnet design. With these magnets, the patient is positioned between flat magnetic poles, leaving access from a range of side approaches. These systems typically utilize lower-field permanent or resistive magnets, with field strengths ranging from 0.064 to 0.3 T, although superconducting mid-field models of this design have also been introduced. The degree of access around the circumference of the biplanar magnet depends upon the number and position of supports separating the two magnetic poles.

A large degree of access around the circumference is afforded by the 'C-arm' design, produced by Siemens Medical Systems (Erlangen, Germany) and Picker International (Highland Heights, OH). In this design, a single column on one side

Figure 1 The C-arm system for percutaneous intervention. Intervention MR suite set up for radiological intervention demonstrates two-camera video sensor array (curved black arrow), which detects the location and orientation of a hand-held probe or needle guide (straight white arrow). The system automatically acquires continuous MR images based on the probe position and automatically updates display of four images on a shielded LCD monitor adjacent to the scanner (straight black arrow). A computer mouse on the LCD console (curved white arrow) and foot pedals (not shown) allow the scanner to be fully operated by the radiologist throughout the procedure

of the patient supports the upper pole, allowing access from the contralateral side, head, and foot end of the magnet (Figure 1). Several manufacturers produce biplanar systems with two supporting posts, resulting in slightly more restricted access to the patient. These include systems produced by Fonar Corporation (Melville, New York), Hitachi Medical Corporation of America (Twinsburg, OH), and General Electric Medical Systems. There are also designs with four support posts from Toshiba America Medical Systems (San Francisco, CA) and Fonar Corporation. The biplanar concept has the advantage of a fairly homogeneous static magnetic field but is limited to lower field strengths than available with the cylindrical superconducting designs. The side access provided by these systems is analogous to that of C-arm fluoroscopy and is amenable to needle or catheter-directed procedures. However, anterior or posterior interventional approaches require decubitus or oblique positioning of the patient, which may not be possible with large patients because of relatively limited space between the poles of the biplane magnet. A true direct vertical approach to the patient is only possible when the patient table is brought outside of the magnet, essentially excluding simultaneous vertical intervention and imaging.

2.4 Other Systems

Other concepts for intervention have also been evaluated, although these systems are still in earlier stages of development. A biplanar design with a very large interpole distance approaching a 'flat bed' scanner was also recently described by Fonar Corporation, but this is still in development. Most likely,

different system designs will be advocated for different interventional applications. The choice of interventional system will depend upon each institution's optimal balance between the types of procedure to be performed, required image quality, and financial constraints.

2.5 Supplemental Technical Developments

There are several recent technical developments that are common to many of the magnet and system designs discussed above and that have facilitated the guidance phase of interventional procedures in a time-efficient manner. First, the construction of higher-quality low-noise receiver chains has allowed lower field systems to be constructed, providing relatively high SNR images and greatly improving image quality compared with earlier attempts at low-field MRI. These systems now provide image quality sufficient for the procedure-guidance phases of minimally invasive procedures. Image acquisition times of 1–3 s per image, or less, provide the necessary temporal resolution.

The second development that has impacted on the use of MR methods for procedure guidance has been the modification and development of rapid gradient echo pulse sequences for use in interactive guidance during device placement. Rapid gradient echo sequences have been developed to allow a wide range of tissue contrast in a time frame sufficient for device tracking (0.3–7 s per image) even at low field strength and with the suboptimal coil position sometimes required to access the puncture site (Figure 2).^{16–19} Because the area of interest to the interventionalist is often limited to a small portion of the entire image acquired, a number of strategies have been proposed to decrease the imaging time for these methods further. These strategies include alternative reconstruction techniques such as Keyhole imaging, singular value decomposition, and wavelet encoding.^{20–32} The use of these rapid gradient echo techniques for guidance of interventional procedures also takes advantage of the reduced needle artifact at lower fields compared with that at 1.5 T, allowing a wider choice of materials for device construction and still allowing high spatial accuracy despite the increased metallic artifact encountered with gradient echo techniques.^{33,34}

The third innovation of significant benefit for MR-guided intervention has been the development of an interface between an optically-linked 3D digitizer and the measurement control software of the MR imager. Previously, frameless stereotactic systems had been used primarily for surgical guidance based on historical imaging data sets. The ability to acquire MR images rapidly and interactively in an arbitrary plane determined by a hand-held, sterilizable probe, or other interventional device, allows rapid planning and confirmation of complex trajectories for rigid instruments. This type of interactive image-guidance system was first described as a component of the 'double donut' system and subsequently has been applied for guidance of image acquisition on C-arm systems (Figure 1).^{12,18}

An additional technical factor facilitating near-real-time procedure guidance has been the ability to view images in the magnetic field through the development of in-room high-resolution rf-shielded monitors.^{12,18,35} In combination with the patient access allowed by open-imaging systems, the ability to view images at scanner side allows the entire procedure to be

performed with the operator sitting next to the patient, with no need to remove the operator's hand from the interventional device at any time (Figure 1). This manner of intervention, analogous to an angiographic or sonographically guided procedure, is well-suited to the skill set developed by radiologists during more conventional types of image-guided intervention.

3 MR-SPECIFIC ISSUES FOR INSTRUMENT GUIDANCE AND VISUALIZATION

Unlike guidance by X-ray-based techniques such as fluoroscopy and CT, there are a number of user-defined imaging parameters and needle trajectory decisions that can markedly alter needle visibility and, therefore, accuracy and safety of MR-guided procedures.³³ The primary factors affecting needle visibility in clinical application can most simply be divided into those dependent upon the pulse sequence and those dependent upon the needle.

The most important pulse-sequence issue with regard to needle visibility is the sensitivity of the sequence to magnetic susceptibility effects.³³ At our institution, as in other recent reports,^{12,18,35–37} near-real-time imaging for primary needle guidance is performed with gradient echo pulse sequences, taking advantage of the rapid scan time and high SNR of this sequence design. Use of these sequences has the primary advantage of rapid temporal resolution and is extremely useful for guiding needles into lesions 1 cm or greater in size that are not immediately adjacent to major neurovascular structures. At 0.2 T, the apparent width of the biopsy needle under gradient echo image guidance generally ranges from approximately 4 mm for smaller needles to 9 mm for larger needles.³³ Although this degree of artifactual widening is acceptable for larger lesions in areas of low neurovascular density, such as the abdomen and extremities, it is clearly unacceptable for head and neck lesions adjacent to major vessels. The degree of artifactual widening can be reduced by approximately a factor of two through use of a turbo spin echo pulse sequence or higher sampling bandwidth.³³ The use of turbo spin echo pulse sequences should be routinely performed prior to cutting needle biopsy to exclude smaller vessels at the level of the cutting edge of the needle; it will be rarely used as the primary mode of image guidance for lesions immediately adjacent to the carotid or vertebral artery, or for spinal lesions for which precise needle visualization is mandatory (Figures 2–4). Spin echo pulse sequences can also be applied to reduce the artifactual needle widening by a similar factor,³³ but are less useful during procedures because of the longer imaging time necessary to obtain a sufficiently high SNR. Therefore, the use of turbo spin echo imaging for position confirmation or primary guidance should be strongly considered when needle placement within 5 mm of major neurovascular structures is contemplated (Figure 3), rather than relying on the more rapid gradient echo sequences for guidance of the entire procedure.¹⁸

The second sequence-related parameter that can be easily varied to adjust the degree of artifactual widening is less intuitively obvious but has had significant clinical utility in our experience. This variable is the direction of frequency encoding relative to the needle shaft. The presence of a needle within tissue creates a local nonuniform spatial distortion in the magnetic field and, therefore, a variation in the local resonant

Figure 2 An 89-year-old woman with Warthin's tumor of the parotid gland. The inferior approach to the parotid tail lesion in this patient allowed this 18-gauge side-notch cutting needle to be placed in the lesion without traversing normal parotid gland and without risk to the facial nerve and its branches. (a,b) Two images from true fast imaging with steady-state precession (FISP) sequence (11.7/5.9/1/90° TR/TE /number of signal averages/flip angle) frames obtained at approximately 1 image per second during advancement of the inner stylet of this core biopsy needle (arrows). (c) A higher resolution turbo spin echo T_1 -weighted image (500/24/1 TR/TE /number of signal averages, 70 s scan time) was obtained to confirm the needle (arrow) position prior to obtaining the core biopsy. (Reproduced with permission from Lewin et al.¹⁸)

Figure 3 A 50-year-old subject with recurrent squamous cell carcinoma of the oropharynx. Turbo spin echo T_1 -weighted image (500/24/1 TR/TE/number of signal averages) clearly documents needle position (arrow) and cutting notch location, particularly important when biopsy is performed near the internal carotid artery (arrowhead) or the larger branches of the external carotid artery. The external carotid artery in this patient had been previously occluded with Gianturco coils to control oropharyngeal bleeding. The coils did not result in significant image distortion and did not preclude biopsy

frequency. For imaging, a spatially linear gradient is used to encode location in the frequency-encoded direction, imparting a linear one-to-one mapping between frequency and position. The local field distortion resulting from the needle disrupts this linear relationship and leads to image artifact along this axis.

Figure 4 Needle position confirmation in a 43-year-old man with leukemic infiltration (chloroma) of scalene muscle. Coronal turbo spin echo T_1 -weighted image (680/24/1 TR/TE/number of signal averages) demonstrates 18-gauge side-notch cutting needle (arrowheads) with stylet extended into the patient's right thoracic inlet paraspinal mass. (Reproduced with permission from Lewin et al.¹⁸)

When frequency encoding is perpendicular to the needle, this results in artifactual widening. When parallel to the needle, this results in less obvious artifact at the tip and hub of the needle. Depending upon needle composition and orientation, swapping the frequency and phase-encoding axes relative to the needle shaft can reduce or increase the apparent width of the needle by a factor of 0.33 to 2.5 for turbo spin echo sequences.³³ This effect can be used to decrease the apparent needle width when the needle artifact obscures adjacent anatomic structures by setting the frequency-encoding axis of the image parallel to the needle shaft.¹⁸ In the presence of even mild respiratory motion, the needle tip for thinner (e.g., 22 gauge) needles can be difficult to visualize in tissue with certainty. Therefore, this effect is more commonly useful, in our experience, to identify the needle tip location more confidently on turbo spin echo images by maximizing the needle artifact through frequency encoding the image in a direction perpendicular to the needle shaft. This ability to alter the appearance of the needle significantly is used on a daily basis in a variety of clinical settings.

Several other important factors are related more to the needle and its trajectory rather than to the pulse sequence and imaging parameters. The dependence of visualization for safe and accurate biopsy on needle composition is obvious and has been well described in many reports since the inception of MR-guided procedures.^{2,3,33} The optimal material for needle fabrication will vary with MR system field strength. Relatively less-expensive materials such as high-nickel, high-chromium stainless steel may be adequate at 0.2 T but may give rise to unacceptable artifact at 1.5 T.^{33,34} Conversely, small-caliber needles constructed from low-artifact materials such as titanium may be difficult to identify in certain clinical settings at low field.

Another issue that may have significant impact on needle localization may be somewhat less obvious: the angle between the needle shaft and the static magnetic field of the MR imager. The apparent needle diameter diminishes markedly from a decrease in artifact as the needle shaft approaches the axis of the static magnetic field.^{2,33,34} Artifacts resulting from field distortion arise most significantly where the field enters and exits objects of differing magnetic susceptibility, such as the needle and surrounding tissue. When the needle is parallel to the field, distortion of the field (and, therefore, image artifact) occurs mostly at the tip and hub, and to a lesser extent along the shaft. The field is increased within the needle shaft. However, because there are no protons to image within the needle, no image distortion occurs. The field is also distorted slightly adjacent to the shaft. At low fields, the distortion adjacent to the shaft is much less than the effect of the applied imaging gradients, and, therefore, little mismapping occurs, with artifact along the shaft primarily related to mild signal loss caused by decreased T_2^* relaxation.

When the needle is perpendicular to the main magnetic field, the field enters and exits throughout the length of the shaft. Local field distortion and, therefore, more prominent artifact can be observed along the entire needle. Although the apparent needle width decreases as the needle is positioned parallel to the static magnetic field (vertically for most biplanar magnets and along the long axis of cylindrical or 'double donut' systems), artifact at the device tip blooms and obscures the true tip position. Steep needle trajectories may be more familiar or appear advantageous in some anatomic locations

but may be prohibited because of this poor needle conspicuity and loss of tip position information. Safe clinical application of MR-guided techniques requires careful consideration of these factors during procedure planning and execution.

4 CLINICAL APPLICATION FOR BIOPSY AND ASPIRATION

Biopsy, aspiration, and cyst drainage represent some of the most straightforward interventional applications for a cross-sectional imaging modality. The tissue contrast, spatial resolution, and multiplanar capabilities of MR have obvious benefits for guidance of biopsy and aspiration applications, and this application was the first reported use of MRI to guide intervention. As noted above, a number of investigators have described the use of MRI for guidance of biopsy and aspiration since the late 1980s.^{3,7-9,18,35,38}

MR guidance for head and neck biopsies has represented a large part of this early literature, owing at least in part to the striking advantages that MR guidance provides for interventional procedures performed in areas of complex anatomy. The benefits of multiplanar image acquisition were quickly discovered by Lufkin and colleagues, who first reported the advantages derived from going beyond the single imaging plane, usually axial, available in CT-guided procedures.⁷ The elimination of beam-hardening artifact, inherent in CT, has also supported the use of MRI for guidance of skull base procedures.^{9,18} Furthermore, the high vascular conspicuity resulting from flow-related enhancement effects inherent in 2D gradient echo imaging is an additional benefit of MR guidance for lesions in regions of complex vascular anatomy.

In our experience, the use of MRI for guidance of biopsy and aspiration has been of most advantage in sampling lesions of the suprahyoid neck, including high cervical spine lesions (Figure 5). The major benefit of MR guidance in this region is the ability to visualize the internal carotid, vertebral, and major branches of the external carotid artery continuously during the entire needle insertion (Figure 6). Masses at the base of the neck, in particular those encroaching upon the brachial plexus, have also presented an excellent application, exploiting the multiplanar capabilities, tissue contrast, and spatial resolution of MRI to allow confident tissue sampling adjacent to the neurovascular structures of the thoracic inlet (Figure 4).^{18,39} The ability to guide needle insertion with continuous imaging has also been helpful for biopsies of laryngeal and pharyngeal submucosal lesions, which are often difficult to define on CT and may be hidden by normal overlying mucosa on endoscopic examination (Figure 7). The T_2 -weighted techniques can also be used to increase diagnostic tissue yield by allowing sampling of non-necrotic regions of complex masses. Rapid gradient echo T_2 -weighted images are also helpful for biopsies and drainages within the spinal canal, in which a clear distinction between cerebrospinal fluid or cyst contents and the adjacent spinal cord is essential (Figure 8).

Other lesions that are particularly well suited to MR guidance are musculoskeletal tumors, for which CT and ultrasound often lack sufficient tissue contrast between pathological and normal muscle. MR-guided needle insertion is also time efficient for contrast injection prior to MR arthrograms.⁴⁰

The use of MR guidance may be less useful for biopsy of abdominal lesions where ultrasound and CT are well suited. In our practice, we restrict the use of MR for abdominal procedures to lesions that are high under the hemidiaphragm,³⁵ liver tumors in which ultrasound and CT fail to provide adequate tissue contrast, and for patients in whom prior ultrasound- or CT-guided procedures have been unsuccessful (Figure 9).

Depending upon the radiologist's preference, biopsies under MR guidance can be performed using free-hand methods, needle holders, or with real-time guidance from optically linked systems, as described above.^{7,12,18,35} Currently, most biopsies at our institution are performed with free-hand techniques, with optically linked frameless guidance reserved for particularly complex procedures. Using the free-hand technique,¹⁸ most biopsies can be performed in less than 1 h of MR table time. For many of these procedures, the rapid frame-rate and high visibility of nearby vessels provided by 2D gradient echo MR techniques allow needle placement in less time than required with CT guidance (less than 8 min per needle pass for both aspiration and core cutting-needle biopsy).¹⁸

Figure 5 A 77-year-old woman with neck pain showing a C2 vertebral body lesion on MRI. The capability to guide biopsy with oblique imaging plane also allows the needle to be angled around the internal carotid and vertebral arteries for biopsy of high cervical spine lesions. Turbo spin echo T_2 -weighted image (2000/105/3/17 TR/TE/ number of signal averages echo train length, 51 s scan time) image obtained prior to sampling with 18-gauge Menghini-type needle. Frequency encoding must be performed perpendicular to the needle shaft with turbo spin echo or spin echo images to maximize needle visualization. Histological diagnosis was plasmacytoma, and the patient subsequently developed multiple myeloma. (Reproduced with permission from Lewin³⁹)

Figure 6 Images from a continuous series obtained at 7 s image with fast imaging with steady-state precession (FISP) sequence (18/7/4/90° TR/TE/number of signal averages/flip angle) obtained during guidance of needle insertion in a 68-year-old man with C1–2 vertebral and prevertebral mass. Previous attempt at surgical transoral biopsy had been unsuccessful. (a) Image early during insertion demonstrates needle tip passing through the left parotid space. An ill-defined mass can be seen in the prevertebral space. High vascular conspicuity resulting from 2D Fourier transform technique allows ready visualization of flow-related enhancement within the internal carotid (curved arrow) and vertebral (straight arrow) arteries. The needle tip (arrowheads) can be interactively directed to avoid these major vascular structures. (b) Mid-insertion, the needle (arrowheads) is interactively redirected more anteriorly once safely beyond the internal carotid artery. Histology demonstrated chronic osteomyelitis and cellulitis and the offending organism was successfully isolated

An additional use of the interventional MRI techniques that form the basis for biopsy guidance is their application for the guidance and monitoring of direct intralesional drug injection, including injection for sclerotherapy of vascular malformations. The same rapid image updates used for interactive needle placement can be used to monitor the injection of sclerosing agents for the treatment of low-flow vascular malformations.⁴¹ The multiplanar cross-sectional images obtained with MR allow the injection of alcohol or other sclerosing agents to be monitored during administration, to ensure filling of the entire targeted portion of the malformation and to exclude extravasation or dissipation of the agent through venous egress.

5 UTILIZATION AND ECONOMIC CONSIDERATIONS

In addition to the many engineering challenges related to MR procedure guidance, the development of appropriate utilization guidelines to optimize cost-effectiveness of these interventions also represents a difficult task. When compared

with current ultrasound- and CT-guided procedures, MR-guided procedures are slightly more expensive (charges for an MR-guided procedure are currently approximately 10–15% more than for a similar procedure under CT guidance at our institution). Therefore, when less-expensive CT or ultrasound guidance is suitable, their use is warranted as the most cost-effective choice. There are a number of procedures in which other imaging modalities lack the tissue contrast or vascular conspicuity to provide safe routes for biopsy or aspiration.¹⁸ It is the procedures for which other imaging modalities are limited or open surgical biopsy is the primary alternative that provide the best area for application of MR-guided techniques.

The most formidable barrier to widespread dissemination of these techniques has been the economic issues related to interventional MRI. The financial resources necessary for an institution to acquire interventional MRI capabilities are often initially considered an insurmountable problem outside of the academic setting. The cost of an interventional system and associated siting depends on several factors, including field strength and system fringe field; the more novel the interventional design, the more expensive it is to acquire. The least-

Figure 7 Chondrosarcoma of cricoid cartilage in a 65-year-old man. (a) A T_2 -weighted image obtained before biopsy shows large cricoid cartilage mass (arrow), stretching the cricopharyngeal muscle posteriorly. (b) Fast imaging with steady-state precession (FISP) ($18/7/1/90^\circ$ TR/TE/ number of signal averages/flip angle) shows coaxial placement of 22-gauge aspiration needle (arrowheads) through 18-gauge introducer needle. MR guidance allowed avoidance of both large and small external carotid artery branches. (Reproduced with permission from Lewin et al.¹⁸)

expensive approach for percutaneous procedures is to add the necessary supplemental equipment for MR-guided procedures to an existing diagnostic MR system. Several vendors offer interventional accessories at prices below US \$160 000, making the variable cost required to perform percutaneous MR-guided procedures relatively low for those sites with pre-existing open MR scanners. Purchase and siting of a low-field system specifically outfitted for intervention, a 1.5 T superconducting short-bore system or the 'double donut' system are each progressively more expensive. As the speed at which procedures can be performed further increases with improvements in MR-guidance techniques, the contribution to fixed cost compared with that of CT-guided techniques should continue to decrease.

Finally, even with the current level of technology and expense, appropriate utilization of interventional MRI can potentially result in a tremendous reduction in the costs associated with treating certain patients. In particular, there has been a marked decrease in cost at our institution for patients for whom the application of MR-guided biopsy or sclerotherapy has avoided an open surgical procedure. This has resulted from a decrease in cost of the procedure itself, relative to surgery, along with equal or more pronounced savings through avoidance of intensive-care unit and routine care hospitalization. This is in addition to the benefit to the patient that results from the reduction in morbidity, mortality, postprocedure discomfort, and time required for recovery when open surgical procedures can be avoided. These potential advantages of interventional MRI have provided the rationale for an increased interest in these techniques, with a growing number of centers and radiology practices developing interventional or intraoperative MRI capabilities. The overall success for this developing field within interventional radiology will require the careful application of these techniques to ensure appropriate utilization. Intraoperative and minimally invasive MR-guided techniques hold tremen-

dous potential, but much effort remains necessary to define their appropriate role in the delivery of cost-effective medical care.

1 INTRODUCTION

Through the technological and clinical advances of the 1990s, MRI has become one of the most powerful noninvasive diagnostic tools in the evaluation of the brain. The superior soft-tissue contrast, the oblique and multiplanar imaging capability, and the absence of ionizing radiation have made MRI the imaging modality of choice for most diagnostic applications of the brain.

These advantages also make MRI an ideal guide for invasive and interventional procedures in the brain. The high sensitivity of MRI to flow enables the delineation of blood vessels without the use of contrast agents. The absence of beam-hardening artifacts from bone and metal devices allows complex instrumentation approaches to anatomic regions that may be difficult or impossible to reach under conventional computed tomography (CT) guidance. Nearly a decade of experience with MR-guided stereotaxis has proven MRI to be an effective and reliable means to visualize and localize neurosurgical targets and a valuable aid in optimizing surgical approaches.¹⁻⁴

Recently, MRI has been applied to treatment monitoring procedures in the brain, such as interstitial therapy and even open surgery.⁵ New developments in MR imaging techniques and MR-compatible instrumentation and the availability of open magnet designs are revolutionizing the role of MRI in guiding and monitoring interventional procedures.

2 MR-GUIDED STEREOTAXIS

Since the mid 1980s, MRI stereotaxis has been successfully employed in neurosurgery to guide biopsies, in tumor resection, deep electroencephalographic (EEG) electrode placement, functional target development and resection, and other

interventional procedures.⁶⁻¹⁴ The noninvasive visualization and localization provided by MRI greatly reduce the surgical invasion necessary to access the target and significantly lower patient morbidity. Several stereotactic systems with localizer frames designed for MRI localization are commercially available: the BRW and CRW (Radionics, Burlington, MA), Leksell (Elekta Instruments Inc., Atlanta, GA), Laitinen (Sandström Trade & Technology Inc., Welland, Ontario, Canada), and others.

Since MRI is more prone to geometric distortion than CT, the accuracy of MRI stereotaxis must be evaluated. The maximum localization error reported in the literature ranges from 1 to 5 mm.¹⁵⁻¹⁸ The variation in the maximum error may be accounted for partly by the use of different stereotactic systems and different reference imaging modalities (CT, ventriculography, etc.) with which MRI is compared. The spatial accuracy of MRI depends on the linearity and calibration of magnetic field gradients and on magnetic susceptibility artifacts, which manifest as spatial distortions. Meticulous quality control should decrease errors in magnetic field linearity and calibration. MRI sequences should use high bandwidth signal acquisition to reduce spatial distortion from susceptibility effects. Several researchers have proposed practical correction algorithms to improve the spatial accuracy of MRI further.^{19,20}

Although accurate and reliable, conventional stereotactic systems require the fixation of a frame to the patient's skull. Recent developments in frameless stereotactic systems will improve patient comfort, localization efficiency, and surgical access in open procedures.²¹⁻²³ Projects are underway to develop MR-compatible navigational systems that use an arm-based three-dimensional digitizer or light-emitting diode (LED)-based optical digitizers registered to the coordinate system of the interventional MR scanner for interactive scan plane control and near-realtime MRI monitoring of the interventional procedure (Figure 1).

3 MR-GUIDED BIOPSY

One of the earliest applications of intracranial interventional MR was to obtain biopsy specimens for tissue diagnosis. As with biopsies elsewhere in the body, the approach utilized for accessing an intracranial lesion is chosen to limit the risk of injury to surrounding vital structures. Either fine needle aspirates or core biopsies can be obtained by utilizing various gauge MR-compatible needles. Also, either frame-based or frameless stereotaxis may be used to guide the approach, depending on the location and size of the target lesion. The primary goal of an intervention within the MR scanner, however, will be a frameless procedure with on-line imaging control of the needle trajectory. The point of entry is determined with an optical tracking device, a gadolinium-filled wand, or simply with the surgeon's finger. Fast image sequences (e.g., two-dimensional fast imaging, with steady-state precession, FISP) allow a near realtime image while advancing the biopsy needle to the desired target. An obvious advantage compared with intraoperative CT is the possibility of taking specimens from different tumor areas best displayed by MRI under direct visual control (Figure 2).

Figure 1 Mechanical articulated arm systems (Operating Arm System Radionics Software Applications, Inc., Burlington, MA) provides intraoperative neuronavigation using a previously acquired three-dimensional CT or MR data set

4 MR-GUIDED ELECTRODE PLACEMENT

Another application of interventional MR is to assist in the placement and in post-placement evaluation of intracerebral depth electrodes.^{24–27} Intracerebral depth electrodes are used to localize the seizure focus in those patients who are refractory to medical therapy. Prior to the development of this technique, such electrodes were placed by inferring their position relative to previously acquired imaging studies. Postplacement examination of electrode placement could not be accurately performed because of the extensive beam-hardening artifact produced in CT by the stainless steel composition of the electrodes. Previously, MR imaging was not feasible because of the ferromagnetic properties of stainless steel and concern for heat and torque production, which could result in local brain injury. With the manufacture of electrodes with different metal compositions, such as platinum alloys, MR imaging guidance can be employed during electrode placement to confirm position without risk of brain injury. Sufficient anatomic detail is obtained to evaluate electrode placement adequately and to avoid possible procedural complications (Figure 3). This should result in improved anatomic–physiologic correlation and surgical outcome for these patients. Intraoperative documentation of long-term implanted depth electrode placed for treatment of chronic pain or movement disorders is another indication in which the anatomical position can be correlated with intraoperative neurophysiological target determination.

5 MR-GUIDED CLOSED MINIMALLY INVASIVE THERAPEUTIC PROCEDURES

In the effort to reduce patient morbidity, hospitalization length, and recovery time associated with conventional craniotomy, several researchers are pioneering new, minimally invasive therapeutic techniques that may achieve results comparable to surgical resection or serve as effective palliative measures. In these minimally invasive procedures, it is particularly appealing to employ MRI beyond mere stereotactic localization and begin to use MRI to monitor treatment administration directly. The sensitivity of MRI to temperature change and other acute tissue effects (e.g. edema) enables the physician to adjust treatment parameters interactively to maximize the destruction of pathologic tissue and minimize undesirable injury to normal tissue.^{28–30}

5.1 Cryoblation

Freezing has been explored as a minimally invasive technique for tissue ablation in the brain. Postoperative MRI of patients who underwent cryothalamotomy demonstrated excellent depiction of the lesions created (Figure 4).³¹ Intraoperative MRI guidance and monitoring of the cryoablation procedure awaits the development of practical MR-compatible freezing devices.

Figure 2 MR-guided biopsy. (a) Direct imaging allows rapid localization of a glioma. (b) MR-guided approach for a deeper lesion

Figure 3 Deep electroencephalographic electrode implantation for patients with medically refractory partial complex seizures who are being considered for possible temporal lobectomy. Coronal MRI was obtained with MR-compatible electrodes in satisfactory position in the hippocampal region

5.2 Ablation by Interstitial Laser Photocoagulation

Traditionally, the use of lasers in neurosurgery has been limited to applications in which direct visualization was possible. Now, MRI guidance allows stereotactic placement of an interstitial laser probe into a deep tumor through a small burr hole in the skull. Laser energy travels through the optic fiber directly into the tumor and produces heat-induced protein denaturation and coagulation necrosis. However, since the penetration and absorption of laser energy are complex functions of tissue characteristics, it is difficult to predict a priori the extent of tissue damage as a function of dose. Therefore, a monitoring technique is required to follow the destructive process in tissue as laser energy is applied. Although CT can show laser-induced tissue changes, these are relatively late findings. Early tissue reaction to laser is missed by CT because of its low soft-tissue contrast.³² Fortunately, many researchers have demonstrated the ability of MRI to detect acute tissue changes secondary to the application of laser energy.^{33–37}

Animal studies have characterized the acute and chronic tissue effects of the Nd:YAG (neodymium:yttrium–aluminum–garnet) laser and correlated the histopathologic findings with their MRI appearance.^{33,35,38} It has been shown that T_2 -weighted images are particularly sensitive to tissue changes and can clearly demonstrate concentric rings of central cavitation, coagulation necrosis, and edema around the point of laser application. Higuchi et al. detected similar patterns in T_2 -weighted images 5 min after laser irradiation in the live rabbit brain.³³

Since the primary tissue effect of Nd:YAG laser irradiation is thermal damage,^{39,40} the thermal sensitivity of MRI can also be exploited to monitor the progress of the laser therapy. The dependence of T_1 -time, diffusion coefficient, water proton chemical shift, and other MR parameters on temperature is well known and has been utilized for noninvasive thermal mapping during the application of laser and other thermal ablation techniques.^{28–30,41–43} Knowledge of the temperature distribution in the treatment area will allow the surgeon to confirm

Figure 4 A T_1 -weighted image obtained several days after stereotactic cryothalamotomy shows the lesion well circumscribed by a hyperintense ring (arrowhead)

the destruction of the target unambiguously while avoiding irreversible thermal damage to vital structures.

Interstitial laser therapy is particularly well suited for intraoperative MRI guidance because the laser-delivering optic fiber is intrinsically MR compatible and because the application of laser energy does not interfere with MR signal acquisition. Initial clinical experience with MR-guided interstitial laser therapy has yielded promising results in the treatment of brain tumors.²⁴ This procedure can be executed under local anesthesia, which allows the neurologic status of the patient to be monitored continuously. MR guidance enables the physician to minimize damage to normal brain tissue, while the absence of systemic toxicity permits repetition of the procedure as necessary.

The Dusseldorf group performed a clinical pilot study of MR-guided Nd:YAG laser ablation on 31 patients with brain tumors. Three-dimensional turbo fast low angle shot (FLASH) sequences were used to determine the position of light guide. The time of irradiation varied from 10 to 20 min. Phase-sensitive two-dimensional FLASH and echo-shifted turbo FLASH were used to generate a color-coded heat map. The result is summarized in Table 1. The study shows that MRI is well suited to monitor laser-induced thermotherapy. A typical laser lesion has a central and peripheral zone that make up the total lesion, and it is circumscribed by an enhancing rim demarcating the outer border of the irreversible damaged lesion (Figure 5).

5.3 Radiofrequency-induced Thermal Ablation

Thermal ablation induced by rf is a technique of tissue destruction by resistive heating using rf (~500 kHz) electrical current. A probe with a conductive tip is inserted into the target, and rf current is then delivered from the tip to cause focal heating; this results in protein denaturation and coagulation necrosis. Over three decades of extensive neurosurgical experience with rf has established the efficacy and safety of this ablation technique.^{26,27,44–52} Ablation with rf has been used primarily for functional neurosurgical procedures including thalamotomy and pallidotomy for parkinsonism and other

Images acquired during treatment; (a) 1; (b) 4; (c) 8; and (d) 10 min after starting the laser therapy. (Courtesy of T. Kahn. In R. Lufkin: 'Interventional MRI', St Louis, 1999, Mosby)

movement disorders, leucotomy for intractable pain, and rhizotomy for trigeminal neuralgia. Postoperative MRI has demonstrated excellent depiction of lesion details in patients who underwent rf thalamotomy.^{44,53,54}

One group has recently completed an initial study of MR-guided rf ablation of primary and metastatic brain tumors.^{5,55} The procedure used MR-guided stereotaxis to place an rf probe (Radionics, Burlington, MA) into the tumor through a 2 mm twist-drill hole in the skull (Figure 6). The rf power was then applied to achieve an intratumoral temperature of 80 °C for 1 min. Depending on the shape and size of the tumor, the probe position was adjusted and additional doses were administered. The entire procedure was performed under light sedation and local anesthesia, which allowed the surgeon to monitor the neurologic status of the patient throughout.

Pretreatment T_1 - and T_2 -weighted MR images provided clear depiction of tumor morphology and anatomic relationships with surrounding vital structures and proved critical in planning the best trajectory for the rf probe. MR angiography with two-dimensional time-of-flight sequences also proved useful to visualize vascular structures surrounding the planned trajectory of the rf probe. The rf lesion was detected in post-treatment MRI as a region of low signal on T_1 -weighted images and as a region of high signal on T_2 -weighted images within 20 to 30

min of the rf ablation. Gadolinium-enhanced T_1 -weighted images demonstrate a rim of enhancement that outlines the zone of tissue necrosis. A total of 15 tumors were treated in 11 patients. During the 2-year follow-up period, seven tumors were controlled by treatment while eight tumors recurred. Five tumors had a durable response to treatment (11.9–23.8 months of follow up; median 15.1 month) (Figure 7). Neurologic complications were few and transient except for one patient, who still had mild expressive speech difficulty at 10 weeks after treatment.

MR-guided rf thermal ablation promises to be a safe, minimally invasive treatment of brain tumors. This technique may become an effective palliative measure and may serve as an adjuvant to radiation therapy. However, unlike radiation therapy, which is contraindicated by accumulative toxicity, rf ablation can be repeated as many times as necessary to treat recurrences. Greater efficacy is anticipated as improved MR-compatible rf generator and therapy probes are developed to allow real-time artifact-free MR imaging of the ablation procedure. As with interstitial laser therapy, the heating effects of the rf ablation can be monitored by temperature-mapping MRI sequences during the application of rf power to confirm the destruction of target tissue before physiologic changes become apparent.

Figure 6 MR-guided rf ablation. (a) The therapy probe is placed into the patient's brain through a 2 mm twist-drill hole using MR-guided stereotaxis. The entire procedure is done under light sedation and local anesthesia in the MR suite. (b,c) Images from two other patients treated in the same way

Figure 7 Contrast-enhanced MR images of a patient who underwent MR-guided rf ablation of a metastatic adenocarcinoma. (a) Image before treatment and (b) immediately after rf ablation. Further images were obtained at (c) 1 week, (d) 5 months, and (e) 1 year after treatment

5.4 High-intensity Focused Ultrasound Ablation

High-intensity focused ultrasound (HIFU) is a new technique of thermal ablation by remote heating. An extracorporeal ultrasound transducer focuses vibrational energy to a point inside the patient's body so that only the tissue within a small focal zone is heated to lethal temperatures (60 °C or above for thermal coagulation and protein denaturation) while the surrounding tissue experiences only a slight temperature increase. HIFU ablation under ultrasound imaging guidance has been used in clinical trials to treat glaucoma, benign prostatic hyperplasia, tumors of the brain, the breast, the liver, the kidney, and the bladder.^{56–60} The greatest advantage of HIFU over other thermal ablation techniques is that no surgical invasion is required to access the target provided there is a sonic path clear of bone and air. However, noninvasive methods to measure the temperature of the focal heating zone must be developed to provide adequate control.

By combining the high soft-tissue contrast and the temperature sensitivity of MRI with HIFU ablation, a powerful minimally invasive therapy technique can be developed. Several researchers have demonstrated the feasibility of using MRI to guide and monitor HIFU ablation procedures.^{41,43,61,62} Fast T_1 -weighted gradient echo sequences can be used to track in realtime the high-temperature focal zone, which appears as a hypointense region, to guide the positioning of the ultrasound transducer. Tissue changes secondary to HIFU heating can be detected easily on T_2 -weighted images, as with interstitial laser therapy. Although practical application of HIFU to the intracranial region necessitates the removal of a skull bone flap to expose the dura, surgical invasion of the brain parenchyma can be avoided and the potential for infection and other complications greatly reduced. Clinical application of HIFU in

neurosurgery awaits the further development of MRI-compatible HIFU therapy systems and MRI temperature-mapping techniques.

6 CONCLUSION

MRI has traditionally been criticized as an expensive diagnostic technology. However, when compared with more costly open surgical procedures and the associated higher patient morbidity, hospitalization costs, and lost time from work, MRI-guided minimally invasive interventions can potentially lower the final cost of medical care in selected patients. More work is clearly warranted in this exciting field to determine its ultimate areas of application in neurosurgery.

1 INTRODUCTION

Image guidance has historically been an integral part of neurosurgery. The introduction of the operating microscope was a major development that enabled the surgeon to decrease the size of the craniotomy and provided superior surface visualization through magnification and perfect illumination. Nonetheless, its advantages for surgical navigation were confined to the visible surface, and the distance to underlying structures had to be estimated. Subsequently, interactive stereotactic image-guided systems were introduced to yield information on the subsurface structures. This allowed the position of the surgeon's tools or visual field to be interactively correlated anatomically with preoperative computed tomographic (CT) or MR images.¹⁻⁸ However, image-guided systems that are based on preoperative imaging cannot account for tissue shifts that occur during the course of surgery.⁹ This has ultimately led to the development of intraoperative imaging techniques. One modality that can be used is ultrasound. Although the image quality of intraoperative ultrasound has improved in recent years, it is still inadequate as the sole means for guiding neurosurgical procedures.

Intraoperative MRI would appear to be an ideal imaging modality for guiding neurosurgical procedures. The inherent multiplanar capability of MRI facilitates interactive selection of imaging planes in near-realtime. Conventional T_1 - and T_2 -weighted images provide exquisite sensitivity for identifying abnormalities within the brain. In addition, specialized imaging sequences are available. These include MR angiographic techniques for mapping blood vessels, dynamic gadolinium-enhanced imaging, functional imaging to map cortical activity, and optimized gradient-echo sequences for early identification of blood products.^{10,11}

The design of new open-configuration MRI systems combined with the development of MR-compatible surgical instrumentation, anesthesia equipment, and monitoring devices has made intraoperative MRI-guided neurosurgery a reality. At Brigham and Women's Hospital, over 400 neurosurgical procedures have been performed using intraoperative MRI guidance. Design and operational features of the intraoperative

MRI system will be described, and our clinical experience with neurosurgical procedures summarized.

2 INTERVENTIONAL MRI DESIGN

Several magnet configurations are currently used for MRI-guided procedures. These include modification of the conventional long-bore configuration, a short-bore design, a horizontal gap open configuration, and a vertical gap open configuration. While the conventional closed long-bore configuration will provide the highest image quality, it offers the least patient access. However, noninvasive energy sources such as high-energy focused ultrasound can be integrated into long-bore MRI systems; the imaging capabilities of the 1.5 T magnet allow prelocalization with subtherapeutic temperatures prior to high-energy ablation.^{12,13} The closed short-bore configuration with flanged bore openings provides improved patient access and maintains the high image quality of a high-field system; however it is not easily amenable for perioperative applications. The open-configuration horizontal gap MRI design allows access to the patient from the sides, permitting most radiologic percutaneous procedures to be performed. The low field minimizes the need for shielding of equipment but also potentially limits imaging capability. Currently, the overlying magnet structure precludes open surgical procedures while the patient is within the imaging field.

Both conventional closed-bore and horizontal open configuration MRI designs can be used intraoperatively by performing surgery outside of the magnet and physically moving the patient into the imaging field for scanning. This must be accomplished while maintaining sterility and is further complicated by the presence of equipment for anesthesia and monitoring the patient. In 1998, Hall et al. reported on perioperative MRI using a conventional 1.5 T system for guiding pediatric neurosurgery.¹⁴ Although the patient had to be repositioned in the magnet for each set of images, these authors point out that the use of the high-field imager allowed state-of-the-art pulse sequences to be used and enabled images of the highest quality to be obtained. In 1997, Tronnier et al. reported on the use of a 0.2 T horizontal-gap open-configuration magnet for intraoperative neurosurgical guidance on 27 patients.¹⁵ The advantages of direct MRI visualization during biopsies, cyst aspiration, and catheter placement procedures were realized. For open craniotomy procedures, however, the patient had to be transferred into the magnet for each imaging set. Newer horizontal-gap MRI units are being designed with improved access, which may permit intraoperative imaging without moving the patient.

In 1993, a vertical gap mid-field strength MRI system was developed as a collaborative effort by General Electric (Signa SP, Milwaukee, WI, USA) and Brigham and Women's Hospital (Figure 1). By allowing vertical access to the patient, this is currently the only interventional MRI design that permits imaging during surgical procedures without moving the patient. The MRI system has been previously described in detail,^{11,16-22} and consists of two vertically oriented superconducting coils (55 cm inner bore diameter) in a modified Helmholtz configuration separated by a 56 cm gap. This spacing permits access to the patient from both sides and allows the surgeon and assistant to work simultaneously in the operating field. Other design

(a)

(b)

Figure 1 Interventional/intraoperative MRI system (GE Signa SP) features a vertical gap for surgical access, and is sited within an operating room. (a) Side view: liquid crystal display monitors mounted at eye level on either side of the magnet allow interactive visualization of the MR images. Connections for headlamps, suction, navigation, and other instrumentation can be seen on the side of the magnet structure. (b) End-on view: MRI-compatible anesthesia and patient monitoring equipment are shown to the right

features included the use of niobium tin as the superconducting material, which has a higher transition temperature and allows the static field to be maintained without a liquid helium bath, thus permitting a wider gap for patient access. The design results in an imaging volume having a 0.5 T static field defined by a 30 cm sphere in the center of the open magnet bore. Flex-

ible transmit/receive coils have been designed to be placed on the patient in close proximity to the imaging volume, while simultaneously allowing surgical and interventional access. The MRI system is maintained in an operating room environment, with adjacent clean and scrub areas. Disposable sterile drapes have been designed to fit within the surgical space of the mag-

net (Baxter, Deerfield, IL, USA). The design considerations for the intraoperative MRI interventional suite have been previously reported in detail.²⁰ Considerations for safety and imaging compatibility in the MRI environment have been reviewed,^{20,23} and appropriate materials are available that have low magnetic susceptibility and minimal effect on local MRI.²⁴ Anesthesia equipment, surgical instruments, patient monitors, and electrocautery devices have already been modified by the manufacturers to be MRI compatible. Specialized devices such as the neurosurgical head holder (Mayfield; Ohio Medical Instrument Co., Cincinnati, OH, USA), flexible Bookwalter arm (Codman Inc., Burlington, MA, USA), pneumatic neurosurgical drill (Midas Rex, Ft Worth, TX, USA), ultrasonic aspirator for neurosurgical resection (Selector; Elekta, Atlanta, GA, USA), and MR-compatible microscope (Studer Medical Engineering, Rhenfaal, Switzerland) have also been developed and are used routinely at our institution.¹⁶

The environment of the MRI system permits it to be used for both *interventional* and *intraoperative* applications.²⁰ Although open surgery is by definition not a minimally invasive procedure, image guidance can, with accurate targeting and presurgical planning, minimize the damage to healthy tissue and maximize removal of the abnormality; this reduces the invasiveness of the surgical intervention. We summarize below our experience with MRI-guided interventional and intraoperative intracranial procedures using the vertical gap 0.5 T MRI system. To date, approximately 300 tumor resection procedures and 100 intracranial biopsies have been performed by our group with intraoperative MRI guidance. Other procedures have included evaluation of cystic lesions by injection of dilute gadopentetate dimeglumine,²⁵ laser ablation of intracranial tumors,²⁶ and endoscopic sinus surgery.^{27,28}

2.1 Interactive Image Guidance

During the MRI-guided neurosurgical procedures, the patient's head is immobilized with a head frame and maintained in the same position throughout the procedure. This provides several important advantages for image guidance. First, patient movement is minimized during imaging. Second, identical slice positions can be obtained and compared during the procedure. Finally, other three-dimensional imaging data sets, such as preoperative MRI, SPECT (single photon emission computed tomography), or PET (positron emission tomography) scans can be co-registered with the MR images and utilized for planning approach and therapy.^{29–35} It should be emphasized, however, that although the skull is fixed in position, we have observed that spatial shifts and deformations occur within the brain during the course of surgery, and anatomic co-registration to preoperative imaging studies alone can be subject to significant errors. This problem of tissue shifts may be minimized if access for biopsy or therapeutic probes is limited to small burr holes. In addition, computer models are under development to account for this problem.^{36,37}

2.2 Interactive Imaging Tools

Optical, acoustic, and rf techniques have been used to establish the location of biopsy needles or interventional probes in three-dimensional space, and this technology is commonly applied to frameless stereotactic surgery where target coordi-

nates are defined based on preoperative imaging.^{1–8} The intraoperative MRI unit features built-in optical (Flashpoint; Image Guided Technologies Inc., Boulder, CO, USA) and rf (CRD; GE Medical Systems, Inc., Schenectady, NY, USA) tracking capabilities.

Tracking by rf can be implemented using miniature coils mounted on the surgical device.^{38,39} Unlike optical or acoustic tracking, intervening tissues are not a problem with rf localization, and this technique is ideal for endoscopic or intravascular procedures.

Currently, the optical tracking system is used for most procedures at Brigham and Women's Hospital. Three charge-coupled device (CCD) cameras are mounted over the imaging field in the MRI unit. These detect infrared light-emitting diodes (LEDs) that are, in turn, attached to the interventional probe. Since the spatial relationship between the LEDs and interventional probe is fixed, the position of the LEDs can be used to define an imaging plane either containing or perpendicular to the probe. Knowledge of the length of the probe allows localization of the probe tip or its projected location. Coordinates of the probe are determined through an interactive workstation (Sun Microsystems, Mountain View, CA, USA), which, in turn, is used to prescribe imaging planes to the SP scanner. Images are subsequently acquired and displayed to the surgeon or interventionalist on liquid crystal display (LCD) monitors which are mounted at eye level on either side of the work area for the MRI (Figure 1). Images are updated every few seconds, reflecting adjustments in probe position and providing visual feedback in near-realtime. For *interactive imaging*, the interventionalist or surgeon uses the interactive probe to navigate through the region of interest, in a manner similar to that utilizing ultrasonography. This technique is particularly useful for establishing the relationship between surface landmarks and underlying structures, and for planning the approach for biopsy or surgical exposure. For needle biopsies or placement of therapeutic probes, the *targeting* mode is particularly useful. Annotation is added to the acquired images in the form of a 'virtual needle', which enables the operator to view the proposed needle path and tip. The trajectory and target can then be verified by imaging in three orthogonal planes, and the operator is provided with near-realtime visual feedback. When the desired trajectory and target point has been established, the interventional probe can be advanced in a stepwise fashion and observed on the MR images as they are acquired in near-realtime; this is termed the *tracking* mode and confirms satisfactory positioning of the biopsy needle or therapeutic probe.

Two optical tracking handpieces are available for attachment to interventional probes (Figure 2): one has three localization LEDs in a triangular configuration that form a plane perpendicular to the probe. This device can be fixed to the surgical table with the Bookwalter clamp and is the handpiece of choice for intracranial biopsies. One of the three LEDs is offset relative to the other two, and this LED along with the biopsy needle defines a reference imaging plane that contains the needle trajectory. Other planes containing the needle can be selected by physically rotating the handpiece and/or by specifying a relative rotation through the interactive navigation software. This is done at the workstation under the direction of the radiologist and MR technologist. In addition, the software allows the plane perpendicular to the needle to be imaged at

Figure 2 Navigational tools feature either two or three LEDs (white arrows) for optical tracking by three cameras mounted overhead in the MRI unit. The two-LED device (left) is used to establish the trajectory of a biopsy needle attached to the end of the handle and is generally used for interventions involving the abdomen, pelvis, or extremities. In the three-LED handpiece (right), the probe is positioned perpendicular to the handle and is typically immobilized using a Bookwalter clamp during neurosurgical procedures. Near-realtime annotation is used to establish the needle trajectory (Figure 3), after which the biopsy needle is advanced under MRI observation

any desired depth relative to the needle tip. The needle length is specified, and software annotation provides a projected tract, or ‘virtual needle’ that can be interactively directed to the target lesion by positioning the handpiece.

The second handpiece for optical navigation (Figure 2, left) features two LEDs mounted on a handle that defines the trajectory of the interventional probe. This device is used most frequently for non-neurosurgical applications, such as interventions in the abdomen, pelvis, or soft tissues.¹⁹ With the two-LED handpiece, the reference imaging plane is defined to be the plane containing the interventional probe and perpendicular to the ground. Other planes can be selected through interactive software prescription.¹⁹

Although used routinely for biopsy procedures, the optical navigation system can be similarly utilized to position other catheters or needles (e.g. for cyst evaluation or drainage²⁵) or to place thermal ablation probes.²⁶

3 MRI-GUIDED BIOPSY PROCEDURES

Interactive MRI guidance offers several advantages over conventional stereotactic biopsy techniques. Conventional stereotactic procedures require the placement of a head frame on the patient followed by a set of preprocedure CT or MR images to define target coordinates. A significant advantage of interactive guidance is that it eliminates the need for this two-step process. The MRI sequence best defining the target tissue

can be selected for image guidance; gadolinium contrast can be injected prior to biopsy; this is usually done after the burr hole or craniotomy has been made and the dura exposed. Perhaps the most important advantage of interactive MRI guidance is that the actual path of the biopsy needle can be followed as it is advanced toward the lesion, and small compensatory changes can be made until the sampling port is positioned within the target. Imaging can then confirm in all three dimensions that the biopsy site lies within the tissue having the abnormal MR signal. The ability to make realtime adjustments of the biopsy needle, along with confirmation of biopsy location, may significantly reduce sampling error, as well as decrease the number of needle passes. This can lead to higher diagnostic yield with reduced morbidity.

Of the nearly 100 MRI-guided intracranial biopsies performed to date at Brigham and Women’s Hospital, approximately two thirds were performed under general anesthesia with the remaining one third performed using monitored conscious sedation. Average procedure time was less than 2 h if general anesthesia was used, and approximately 1.5 h when conscious sedation was utilized. For navigational MRI, sequences were selected to define the target best. For enhancing lesions, 10–20 ml intravenous gadopentetate dimeglumine was injected, and T_1 -weighted fast spin-echo (FSE) images used (updated every 14 s). For nonenhancing lesions, T_2 -weighted FSE imaging was usually used (updated every 15–30 s). More recently, a SSFSE (single-shot fast spin-echo) protocol has been developed that allows T_2 -weighted images to be acquired every 4 s. An example of a biopsy performed using

Figure 3 Interactive MRI for biopsy of a right frontal lesion using the 3-LED handpiece and T_1 -weighted images following intravenous gadolinium enhancement. (a) Para-axial image perpendicular to needle in the plane of the biopsy port allows targeting of enhancing margin. (b) Para-sagittal image in the plane of the needle shows the 'virtual needle' depicted as dashed lines directed at the target. Note the small signal void at the cortical surface from the biopsy needle tip prior to insertion. (c) As the titanium needle is advanced, near-realtime imaging allows observation of the needle tract along the virtual needle annotation. This allows fine adjustments to be made accordingly and enables the position of the actual biopsy needle to be confirmed prior to sampling. (d) Actual needle tract is confirmed in the perpendicular para-coronal plane. The tip of the virtual needle corresponds to the level of the sampling port of the biopsy needle; as a result the actual needle tip extends a few millimeters beyond the dashed annotation. Note focal signal void within the enhancing rim from biopsy sample

MRI-based navigation is illustrated in Figure 3. In this case, contrast-enhanced T_1 -weighted imaging was used for guidance. After the patient has been positioned in the headholder on the MRI operating table, the handpiece may be used in the interactive imaging mode to plan the incision location and biopsy trajectory. Prior to inserting the biopsy needle, the targeting mode is utilized, with annotation used to define a virtual needle. The target position can be confirmed in three orthogonal planes (Figure 3). With the handpiece immobilized with the Bookwalter arm, the titanium biopsy needle is advanced in a stepwise manner as MR images are acquired. The needle is observed as a signal void overlying the virtual needle annotation (Figure 3c,d). It should be noted that the tip of the virtual needle is set to correspond to the location of the sideport of the biopsy needle; therefore, the actual needle tip extends several millimeters beyond the virtual needle annotation. This confirms that the biopsy needle is traveling along the expected trajectory

and to the desired target depth. If necessary, the annotation can be removed to allow the actual needle location to be seen more clearly and reconfirmed in all three planes. The ability to confirm that the biopsy specimen was obtained within the MR-defined abnormality minimizes sampling error and potentially reduces the number of needle passes and associated complications.

4 MRI GUIDANCE FOR OPEN CRANIOTOMIES

Since 1996, approximately 270 open craniotomies have been performed at Brigham and Women's Hospital for MRI-guided tumor resection. Patient selection, demographics, and preliminary clinical results have been previously reported.^{11,16,18,22} In preparation for surgery, the patient's head is

positioned in the MRI with the head holder to allow the best surgical access. As a result, the patient's anatomic frame of reference no longer corresponds to conventional MRI planes. To overcome this problem, a new frame of reference is established to allow true axial, sagittal, and coronal images to be obtained. This can be easily accomplished using the navigational tools previously described; interactive imaging is used to define an appropriate reference imaging plane from which conventional axial, sagittal, or coronal images can be prescribed. Since the patient is immobilized, the reference imaging procedure need only be performed once and is typically done immediately after the patient has been positioned within the intraoperative MRI. The use of conventional imaging planes facilitates accurate localization and identification of critical anatomic structures as the surgery progresses. During the procedure, the radiologist prescribes the appropriate imaging planes and sequences that will best address specific questions of the surgeon as the surgery progresses. For example, for initial identification of tumor boundaries, either conventional spin-echo gadolinium-enhanced T_1 -weighted images or T_2 -weighted images may be most useful. Other specialized imaging sequences have been developed, including SSFSE for rapid T_2 -weighted imaging, dynamic contrast-enhanced imaging, susceptibility sensitive sequences to evaluate early hemorrhage,^{10,11} and rapid volumetric image acquisition techniques.

In patients who have been previously treated with high-dose radiotherapy (stereotactic radiosurgery), it is not possible to distinguish active tumor recurrence from postradiation necrosis on conventional delayed gadolinium-enhanced images. Dual-isotope $^{201}\text{Tl}/^{99\text{m}}\text{Tc}$ -HMPAO (hexamethylpropyleneamine oxime) SPECT scanning has been found to be useful for making this important distinction,^{33,34} and these images can be co-registered with intraoperative MR images. Alternatively, a dynamic contrast-enhanced MR study can be performed. These techniques have been useful for estimating tumor grade as well as for distinguishing recurrent tumor from post-treatment change.⁴⁰⁻⁴² Our intraoperative technique is to obtain two-dimensional fast spoiled gradient-echo images through the tumor volume, with each slice sampled every 11–15 s for 2–3 min following rapid bolus contrast injection. Tumor recurrence, with associated neovascularily, will tend to enhance early, while post-treatment necrosis, related primarily to blood–brain barrier breakdown, will tend to show delayed enhancement. Distinguishing active recurrence from radionecrosis is valuable both for selecting appropriate biopsy sites and for planning the surgical resection. This has been very useful in the intraoperative setting. In an evaluation of a series of 24 patients with intraoperative dynamic MRI,⁴³ 14 of 15 lesions demonstrating early enhancement had recurrent tumor by pathology; out of the nine lesions that did not show early enhancement, eight had only reactive post-treatment changes. In this study, early enhancement was determined visually when the appearance of contrast within the lesion occurred at the same time as in vascular structures or the choroid plexus.

For all intraoperative MR, an initial baseline set of two-dimensional slices is obtained through the volume of interest. Imaging is repeated at intervals during the surgery to verify the present location in relation to the remaining tumor to be excised. Additionally, the location of the surgical resection cavity relative to adjacent eloquent cortical pathways is always of

major importance. Once the most appropriate imaging sequence and imaging plane have been preloaded into the MR console, identical image slices can be acquired simply by rescanning. This allows direct serial comparison in the same imaging plane. Acquisition time for each imaging data set varies depending on the imaging sequence but takes approximately 1–2 min. Prior to imaging, electrical equipment and metallic instruments are removed from the surgical field. Although these devices are MRI-compatible they can produce significant imaging artifacts if they are left in place. Imaging is possible, however, with the operating microscope in position. In our experience, intraoperative MRI guidance enables the surgeon to verify his or her planned approach and surgical procedure and also allows him or her to change the strategy during the procedure according to the newly acquired information.

Figure 4 illustrates an MRI-guided tumor resection. In this case, T_2 -weighted images were used for surgical guidance. Serial images from a single axial slice are shown in this example. Early in the procedure, the resection site was defined by a locator. The tissue anterior to this (white arrow, Figure 4(a)) was felt to represent non-neoplastic changes after previous surgery, and this was confirmed by intraoperative histopathology. The remaining tumor was represented by a high T_2 signal posterior to the pointer and just anterior to the motor strip. Stepwise resection of the tumor is illustrated in Figure 4b,c, with complete resection shown in Figure 4d. Prior to closing, the cavity was irrigated with saline (Figure 4e), and multi-echo gradient-echo images were obtained to evaluate for significant hemorrhage. The MRI characteristics of hyperacute intracranial hemorrhage have been recently described.²⁵ In our experience, T_2 -weighted images (FSE, $TR/TE=4000/100$ ms; Figure 4e) in combination with gradient-echo sequences (30° flip angle, $TR=600$ ms) is sensitive for identifying hyperacute hemorrhage and for distinguishing this from postsurgical fluid. Figure 4f,g shows postsurgical gradient-echo images with TE of 9 and 60 ms, respectively. A typical postoperative appearance is illustrated here, with irrigation saline (bright T_2) within the resection cavity, and a thin rim of low signal bordering the resection cavity on the short TE image (Figure 4f) that 'blooms' on the second echo ($TE=60$ ms; Figure 4g). This rim is felt to represent deoxyhemoglobin content within acute blood products at the resection border. No hematoma, mass effect, or extra-axial collection was noted in this patient. Hematomas tend to have a nonfluid central area (lower T_2 signal), with a rim of susceptibility that also blooms on gradient-recalled echo imaging.

Intraoperative MRI-guided tumor resection provides several advantages over conventional techniques. Image guidance is interactive. Specific sequences and imaging planes can be applied during the procedure to optimize selection of involved tissue. For example, dynamic or steady-state contrast-enhanced images can be used to delineate active tumor, and T_2 -weighted images can be used to identify nonenhancing tumor. Neoplastic tissue having abnormal MR signal characteristics but normal appearance visually can be identified and resected. Tissue shifts during surgery have been observed and are easily compensated for with intraoperative imaging. Critical anatomical and functional structures can be identified during resection and, at crucial points in the procedure, images can be obtained more frequently in multiple planes if necessary to refine the resection margin. Finally, imaging capability allows early detection of

Figure 4 Intraoperative imaging during neurosurgical resection: serial T_2 -weighted axial images. (a) Early in the surgery, the neoplastic tissue is posterior to the surgeon's finger. Anterior tissue (arrow) represents postoperative change from previous surgery and was present on prior MR study (b,c) Serial resection, (d) complete resection of the T_2 -abnormal tissue. Some tissue shift is evident. (e) Following resection, the cavity is filled with saline. (f,g) Postsurgical gradient-echo images allow evaluation of hyperacute hemorrhage. These show typical postsurgical changes. (Reprinted with permission from Wong et al.²²)

Figure 5 Intraoperative parasagittal image (note intraoperative pointer, white arrow) co-registered with the patient's preoperative three-dimensional brain model. Operative skin flap in the lower portion of the image on the left. The preoperative model includes conventional MRI with segmentation of tumor (green) and ventricles (light blue). In addition, MR angiography was performed to display large vessels (red). Functional MRI was used to identify cortical activation during complex speech tasks (turquoise and yellow) and motor tasks (magenta)

any unexpected complication, such as hemorrhage. Out of some 400 neurosurgical procedures, postsurgical hematomas were observed in four patients. In all cases, imaging permitted immediate identification, and facilitated removal in three patients. In the fourth patient, serial MR images were used to confirm stability of a small hematoma, and removal was unnecessary. In one patient, a hematoma was noted in the hemisphere contralateral to the surgery and was felt to represent a spontaneous hematoma, possibly from blood pressure instability. This would not have been identified without immediate postoperative imaging; a second craniotomy was performed using MRI guidance to evacuate it.

5 FUTURE PERSPECTIVES

Specialized MRI sequences are available on higher-field MRI units that are not yet available on the intraoperative MRI

system, and sophisticated interactive methods have been developed for preoperative surgical planning.⁴⁴ In addition, other three-dimensional imaging modalities can provide important information not available by MR techniques. Therefore, we have developed co-registration software to integrate preoperatively acquired multimodality information with the intraoperative imaging. Examples of specialized studies that can be performed prior to surgery include MR angiography, PET, SPECT, and functional MRI. MR angiography can define the relationship of the tumor to major vascular structures during the surgical procedure. PET imaging with [¹⁸F]-fluorodeoxyglucose reflects metabolic activity of gliomas, and areas of higher uptake correlate with higher tumor grade and poorer prognosis.^{29–31} Dual-isotope ²⁰¹Tl/^{99m}Tc-HMPAO SPECT is useful for distinguishing tumor recurrence from radiation necrosis,³³ and findings also correlate with histopathological findings and survival.³⁴ Image registration of MRI with PET or SPECT images can, therefore, be useful for directing biopsy to regions most repre-

Figure 6 Surgical planning computer display. Preoperative three-dimensional model (right, upper frame) demonstrating tumor (green) and anatomic relationship to superior sagittal sinus (red), corpus callosum (brown), and ventricle (blue). The bottom row displays three intraoperative sagittal images in the same imaging plane. On the left is the unenhanced T_1 -weighted image prior to craniotomy. The middle image demonstrates enhancing tumor prior to resection and is reproduced in the large upper left frame. The image on the bottom right demonstrates the surgical resection cavity following tumor removal

sentative of tumor behavior; this may reduce sampling error. For image-guided tumor resection, the addition of PET or SPECT data can help the neurosurgeon to select most aggressive portions of tumor for resection. Functional MRI can be

used to map areas of cortical activation during motor tasks, enabling critical sensorimotor areas to be identified and allowing the neurosurgeon to avoid eloquent areas during tumor resection.⁴⁵

The preoperatively acquired information is combined with the intraoperative imaging data set using registration algorithms, thus maximizing the information available during surgery. The grayscale images and three-dimensional models of specific structures are displayed to the surgeon and correspond spatially to the actual patient as positioned in the intraoperative MRI (Figure 5). The combination of the preoperative information and the intraoperative renewal of the grayscale information allows updated neuronavigation. With progress of the surgical intervention and increasing brain deformation, the validity of the preoperative information decreases. We are currently evaluating the definition of a deformation field from the intraoperatively acquired grayscale images to align the three-dimensional models and their preoperative information to the updated situation. Other models to account for brain deformation are being developed.^{36,37} The combination of pre- and intraoperative information, their alignment and the tracking of instruments in this defined space comprise the capabilities of this system for realtime interactive image-guided surgery (Figure 6).

6 CONCLUSIONS

Intraoperative MRI-guided neurosurgical procedures are a collaborative effort, involving neurosurgeons, neuroradiologists, anesthesiologists, MR technologists, nurses, and engineers. MRI provides excellent contrast between abnormal and healthy brain tissue, and intraoperative imaging permits these areas to be defined relative to the surgeon's field of view. This improves the accuracy of intracranial biopsies and surgical resection of tumors. Early identification of unexpected complications is another benefit. To date, MRI guidance has been utilized in selected complex cases or repeat surgery. Based on our current experience, there is little question that MRI guidance for neurosurgical procedures augments the technical capability of the neurosurgeon to remove neoplastic tissue selectively. However, evaluation of cost effectiveness and clinical outcomes relative to conventional neurosurgical procedures will require a prospective, randomized clinical trial.

In the future, technological developments will continue to reduce the degree of invasiveness required for tumor resection. Definition of the tissue targeted for resection and its relationship to critical functional structures will continue to be improved through multimodality presurgical planning. Improvements to MRI will include faster acquisition times and refinement of imaging sequences for neurosurgical guidance. Currently available 'near-realtime' imaging will become closer to realtime. Image processing will continue to become faster, and techniques to compensate for intraoperative tissue shifts and removal are under development. Surgical image guidance will ultimately be a synthesis of anatomical/functional preoperative images with updated co-registered intraoperative imaging.

Image guidance will allow neurosurgeons to treat benign and malignant lesions using minimally invasive tools. Thermal ablation techniques using laser, rf, ultrasound, and microwave energy sources are currently being investigated, as is cryotherapy. Central to the success of these minimally invasive therapies is image guidance to position the ablation probes and monitor the thermal therapy. The navigational tools available

for MRI-guided biopsies described above can be used to position thermal ablation probes accurately. In addition, MRI is uniquely suited to reveal subtherapeutic as well as irreversible thermal effects, and development of improved, faster imaging sequences to monitor these tissue effects will parallel the refinement of energy sources to deliver controlled, directed thermal ablation.

Biographical Sketches

Terence Z. Wong. b 1955. B.S.E. biomedical engineering, 1977, Duke University, M.D. and Ph.D., 1990, Dartmouth College and Dartmouth Medical School. Residency in Diagnostic Radiology, Deaconess Hospital, Harvard Medical School, 1992–96, Fellowship in Nuclear Medicine, Deaconess Hospital 1995–96, Fellowship in Cross-sectional Imaging, Beth Israel Deaconess Medical Center 1996–97, Fellowship in Interventional MRI, Brigham and Women's Hospital 1997–98. Assistant Professor of Radiology, Assistant Professor of Radiation Oncology, and Assistant Professor of Biomedical Engineering, Duke University Medical Center 1998–present. Current research interests: image-guided therapy, multimodality metabolic and functional imaging, selective oncologic imaging and therapy, thermal therapy.

Richard B. Schwartz. b 1956. B.S., 1978, M.D., 1982, Ph.D., 1985, Neuroanatomy, University of Pennsylvania, USA. Neuropathology internship, Tufts-New England Medical Center, Boston MA, 1984–85. Radiology residency, Brigham and Women's Hospital, Boston MA, 1985–89. Neuroradiology fellowship, Brigham and Women's Hospital, Boston MA, 1989. Certificate of Additional Qualification, 1996. Instructor, assistant professor, and associate professor of radiology, Harvard University, 1989–present. Assistant Director of the Neuroradiology division, Brigham and Women's Hospital, Boston MA, 1992–present. Director of Functional and Navigational Neuroimaging, 1999. Approx. 80 publications in CT, MR and SPECT scanning of the brain. Current research interests: intracranial intervention under MR guidance, acute hypertensive disorders of the brain, neurovascular applications of spiral CT, and functional imaging of brain tumors using MR and SPECT.

Arya Nabavi. b 1966, M.D. University of Kiel/Germany. Neurosurgeon, Research Fellow at the Department of Neurosurgery, Brigham and Women's Hospital, Harvard Medical School. Current research interests: application of MR in neurosurgery, image-guided surgery, intraoperative brain deformations.

Richard S. Pergolizzi Jr. b 1964. B.Sc. Chemistry, 1987, The State University of New York at Stony Brook, M.D. 1993, Northeastern Ohio Universities College of Medicine. Residency in Diagnostic Radiology at University of Cincinnati, University Hospital 1993–97, Fellowship in Neuroradiology, University Hospital Health Science Center, Syracuse NY 1997–98, Fellow in Neurointerventional Radiology, Brigham and Women's Hospital and Massachusetts General Hospital, Harvard University, 1998–present. Current research interests: clinical applications for MR image-guided therapy.

Peter M. Black. b 1944, A.B., 1966, Harvard College, M.D. 1970 McGill University, Montreal, Canada, Ph.D., 1978, Georgetown University, USA. Research fellow in Neuro-oncology, Massachusetts General Hospital, 1976, Asst. Professor of Surgery, Harvard Medical School, 1980–84, Associate Professor of Surgery, Harvard Medical School, 1984–86. Franc D. Ingraham Professor of Neurosurgery, Harvard Medical School, 1987–present. Neurosurgeon-in-Chief, Brigham and Women's and Children's Hospitals, 1987–present. Chief of Neurosurgical Oncology, Dana Farber Cancer Institute, 1987–present. Chairman of the Board, Brain Tumor Center, BWH, CH, DFCI, 1988–present. Chairman, Department of Surgery, CH, 1994–98. More than 40 visiting professorships and lectureships. Approx. 155 original articles, 7 books, 150 reviews and book chapters, and several clinical communications. Current major research interests: advanced imaging techniques for surgery including the intraoperative MRI and brain mapping, and in the laboratory, molecular biology of brain tumors, specifically the relation between glial development and glioma formation, and hormonal influences on meningioma progression.

Eben Alexander III. b 1953. A.B., 1975, Chemistry, University of North Carolina, Chapel Hill. M.D., 1980, Duke University School of Medicine, Durham, North Carolina, Intern in General Surgery, Duke University Medical Center, 1980–81. Resident, Neurological Surgery,

Duke University Medical Center, 1981–83. Research Fellow in Neurosurgery, Massachusetts General Hospital, Harvard Medical School, 1983–84. Acting Resident in Neurology, Massachusetts General Hospital, Boston, Massachusetts, 1985. Resident in Neurological Surgery, Duke University Medical Center, 1985–87. Senior Registrar and Cerebrovascular Fellow, Neurosurgical Service, Newcastle General Hospital, Newcastle-Upon-Tyne, England, U.K., 1987. Instructor in Surgery, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts 1988–90. Assistant Professor of Surgery (Neurosurgery), 1990–94, and Radiation Oncology, Harvard Medical School, 1990–99. Associate Professor of Surgery (Neurosurgery), Harvard Medical School, 1994–99. Director of the Stereostatic and Functional Neurosurgery Program, Brigham and Women's Hospital. Approx. 150 publications in neurosurgery, especially radiosurgery and image-guided surgery. Current research speciality: development of advanced synergistic radiation and surgical techniques through image-guidance.

Claudia H. Martin. *b* 1959. B.Mus., 1984, M.D., 1988, McGill University, Canada: Surgical Internship. Yale University, New Haven, 1989–90, NIH postdoctoral fellow in neurosurgery, Bethesda, Maryland, 1990–91, Neurosurgery resident, Yale University, New Haven, 1991–95, Neurosurgery clinical fellow, Brigham and Women's Hospital, Harvard University, Boston, 1996–99. Chief resident Brigham and Women's Hospital, Boston, 1999–2000. Approximately 10 publications in image guided neurosurgery.

Ferenc A. Jolesz. *b* 1946. M.D., 1971, Semmelweis Medical School, Hungary. Resident in Neurosurgery, Medical School Pecs, Hungary, 1971–72. Research Fellow, Biomedical Engineering Computer Sciences, K. Kando College, Hungary, 1972–73. Resident in Neurosurgery, Institute of Neurosurgery, Hungary, 1975–79, Research Fellow, Neurology, Massachusetts General Hospital, Boston, MA, 1979–80, Milton Research Fellow, Physiology, Harvard Medical School, Boston, MA, 1980, Research Fellow, Physiology, Harvard Medical School, Boston, MA, 1980–81, Research Associate, Physiology, Harvard Medical School, Boston, MA, 1981–82, Resident, Radiology, Brigham and Women's Hospital, Boston, MA, 1982–85, Assistant Professor, Radiology, Harvard Medical School, Boston, MA, Director, Neuro MR Imaging Section, Brigham and Women's Hospital, Boston MA, 1987–88, Director, Division of Magnetic Resonance Imaging, Brigham and Women's Hospital, Boston, MA, 1988, Associate Professor of Radiology, Harvard Medical School, Boston, MA, 1989–96, Director, Image-guided Therapy Program, Brigham and Women's Hospital, Boston, MA, 1993–present. Professor of Radiology, Harvard Medical School, Boston, MA, 1996. B. Leonard Holman Professor of Radiology, Harvard Medical School, Boston, MA, 1998. Member of the Institute of Medicine, National Academy of Sciences. Approx. 200 publications. Current research speciality: interventional and intraoperative MRI, quantitative neuroimaging, focused ultrasound surgery.

Temperature Measurement In Vivo Using NMR

Ian R. Young

The Robert Steiner MRI Unit, Hammersmith Hospital, London, UK

1 INTRODUCTION

Philosophically, the desirability of using imaging to monitor therapy as it happens seems indisputable, with the potential this offers for reducing any uncertainty in treatment and for permitting adjustment of treatment as it proceeds to optimize outcome. Allied to the advantages of minimally invasive therapy – reduced patient trauma, shorter duration in hospital – the case for imaging in conjunction with the ablative therapies has seemed excellent. In this respect, because MR has so many potentially useful temperature dependencies, which might allow quantitative measurement of what is happening, it has seemed the modality of choice, and significant research effort has been expended in efforts to convert that perception to reality.

Most of this work has gone into attempts to exploit the thermal dependencies of T_1 and the chemical shift of water; a much smaller resource has been applied to the temperature sensitivity of the diffusion coefficient. Attempts to use T_1 changes have included studies of the relaxation behavior of other nuclei than hydrogen; while chemical shift strategies have employed spectroscopy as well as imaging techniques. All of these approaches will be reviewed in the article. Each method will be covered in a brief section that will include a description of attempts made to use it.

2 TARGETS OF PERFORMANCE FOR IN VIVO TEMPERATURE MEASUREMENT

A prime concern in thermal ablations is to control the extent of any unwanted damage to normal tissue around the lesion being treated. While the temperature in the target region for the ablation may well exceed 60°C, and there is little need to measure its actual level with great accuracy, it is important that temperatures of up to perhaps 45°C be observed with some precision. If precedents from low-temperature rf hyperthermia are applied (in which considerable care was exercised to avoid collateral damage) then the targets for measurement are:¹ temperature accuracy of $\pm 0.5^\circ\text{C}$, volume of interest 5 mm³, and temporal resolution of 30 s.

Temporal resolution is desirably substantially better in therapies such as focused ultrasound, where significant quantities of energy can be deposited in a small volume very quickly, with consequently swift changes in temperature. Spatial resolution cannot be allowed to deteriorate significantly as tissue can support quite considerable temperature gradients (certainly in the range of 5°C cm⁻¹ or more).

3 TEMPERATURE DEPENDENCE OF T_1

Theory predicts a relationship between temperature and T_1 of the general form:

$$\frac{1}{T_1} \propto \frac{\eta}{T} \quad (1)$$

where η is the macroscopic viscosity, and T the absolute temperature.

Over the limited temperature excursions of tissue temperature for which real accuracy is important (see above), there is effectively a linear relationship between T_1 and T . Energy level considerations predict a temperature coefficient of around 1.3% °C⁻¹ for sensitivity of the measurement of T_1 for water;² because this approach to the measurement has been perceived as being the simplest of those that are available, it was the first approach to be investigated.^{3,4}

The usual approach that has been adopted⁴ is to acquire a short TE spin echo, or gradient recalled echo, image with long TR for use as a reference (data set A), then follow this with short TR data acquisitions using the same TE as before whenever needed (data set B). From this T_1 is calculated using the relationship:

$$\frac{S_B}{S_A} = \frac{1 - \exp(-TR_B/T_{1B})}{1 - \exp(-TR_A/T_{1A})} \quad (2)$$

when S_A and S_B are the respective signals from the two data sets; T_{1A} and T_{1B} are the T_1 values at the times of the A and B acquisitions; and TR_A and TR_B are the respective TR values. The methods has been successfully evaluated many times in phantoms and in vitro.⁵⁻⁷

However, it is clear that the relationship in Equation (2) is defective in at least one respect – it assumes that the intrinsic signal is independent of temperature, which, via the Curie relationship, it is not:⁸

$$M = \frac{N\gamma^2\hbar^2 I(I+1)}{3kT} H_o = \chi_o H_o \quad (3)$$

where M is the magnetization arising from an applied field H_o , χ_o is the nuclear susceptibility, N Avogadro's number; γ , $\hbar$ and k are, respectively, the gyromagnetic ratio, Planck and Boltzman constants; I is the spin quantum number.

More exactly, Equation (2) should include an extra ratio on its right-hand side (M_B/M_A) where M_A and M_B are the respective tissue magnetizations; this effectively reduces to (T_B/T_A) using Equation (3), and allowing for the possibility that T_2 is also temperature sensitive, though it seems to be only weakly so in near-normal tissue;⁹ consequently, the ratio in Equation (2) becomes

$$\frac{S_A}{S_B} = \frac{T_A (1 - \exp(-TR_{1B}/T_{1B})) \exp(-TE/T_{2B})}{T_B (1 - \exp(-TR_{1A}/T_{1A})) \exp(-TE/T_{2A})} \quad (4)$$

The problems of obtaining an accurate measurement are compounded by other changes that are likely to take place during actual therapy. For example, when tissue is cooled¹⁰ or heated during thermal ablation,¹¹ it can swell, and this can affect the measurements still further. As noted by Young et

al.,¹² the type of relationship that can be required to describe the changes with real precision (even if a two-component system (p, r subscripts) only is used) can become very complex, as illustrated by Equation (5).

$$\frac{S_B}{S_A} = T_A/T_B \frac{\left\{ x_B \left(1 - \exp\left(-\frac{TR_B}{T_{1Bp}}\right) \right) \exp\left(-\frac{TE}{T_{2Bp}}\right) - (1 - x_B) \left(1 - \exp\left(-\frac{TR_B}{T_{1Br}}\right) \right) \exp\left(-\frac{TE}{T_{2Br}}\right) \right\}}{\left\{ x_A \left(1 - \exp\left(-\frac{TR_A}{T_{1Ap}}\right) \right) \exp\left(-\frac{TE}{T_{2Ap}}\right) - (1 - x_A) \left(1 - \exp\left(-\frac{TR_A}{T_{1Ar}}\right) \right) \exp\left(-\frac{TE}{T_{2Ar}}\right) \right\}} \quad (5)$$

where x is the effective NMR visible fraction of component p present – which is, of course, temperature sensitive itself. Note that x is, using this definition, not, in general, the actual physical fraction of p that is present and so cannot be assessed by purely analytical methods. The potential impact of temperature changes on the fraction of the hydrogen nuclei in a component that actually contribute usefully to the NMR signal is another matter altogether.

Clearly such relationships contain so many variables that can only be known with low, if any, precision at all that T_1 cannot provide an accurate temperature scale within the requirements noted in Section 2.

Figure 1 gives some measure of the impact of these complexities on the measurement temperature in human calf muscle, in an experiment in which the tissue was cooled using water circulated through bags on either side of the leg.¹² The curve $T_{1(R)}$ was plotted from the data set assuming the relationship in Equation (2) was valid, and that the reference measurement (A) was made initially and not checked thereafter. The resultant coefficient of T_1 versus temperature is rather larger (at about $1.6\% \text{ } ^\circ\text{C}^{-1}$) than would be expected. The second T_1 set of data ($T_{1(N)}$) was plotted using Equation (2) again, but, using long and short TR data taken at the same temperature; consequently, to an adequate extent $T_A = T_B$, and the relationship (ignoring the

possibility of there being other components) is tractable. The third curve (proton density) reveals what is happening. It is a plot obtained from the long TR data only, which shows that this is changing at around $1\% \text{ } ^\circ\text{C}^{-1}$, indicating the possible for-

mation of edema and/or increased tissue perfusion. Equation (2) does not then reflect what is happening, and the very low coefficient of T_1 dependence on temperature obtained using it (and plotted as $T_{1(N)}$) is not a true value. The value of T_2 was assumed to be unaffected by temperature in this work.

Nevertheless, the changes associated with variation in T_1 are easy to demonstrate using TurboFLASH or similar sequences,^{5,6} which are available on most scanners. These are probably capable, for example with methods in which the local temperature can be changed very rapidly, such as focal ultrasound,¹³ of a measurement accuracy in the range $3\text{--}5^\circ\text{C}$. As such, they may well not be capable of providing useful data to help to avoid collateral damage, though it will be possible to use them to make sure the temperature of a target region has exceeded a lethal level for cells present there.

4 TEMPERATURE DEPENDENCE OF T_2

The possibility of T_2 being the basis of a temperature scale has been previously noted, through largely discounted. It does not seem to have a useful dependence in vivo in near normal tissue⁹ and has been little investigated as such. There is, however, one circumstance when it could be very significant. This

Figure 1 Temperature and proton density from a region of calf muscle undergoing temperature stress in a volunteer. The curves fitted to the points are $T_{1(R)}$ ($\blacktriangle$), $T_{1(N)}$ ($\bullet$) (both left-hand scale), and proton density curve ($\square$). (Reproduced with permission from Young et al., *Magn. Reson. Med.*, 1994, **32**, 366.)

is in cryoblation, where its application has been extensively studied.¹⁴ The problem with this approach is that it is not sufficient just to freeze the tissue in order to damage it; the temperature must be reduced substantially below 0°C. Conventionally, it would be assumed that once the tissue had solidified no further useful MRI signals would be obtained, and any attempts at tracking further temperature changes would need to be done by computer modeling.¹⁵ However Daniel et al. showed how it is possible to use variations in T_2 of the unfrozen water fraction in the tissue as a means of monitoring temperature.¹⁴

5 TEMPERATURE DEPENDENCE OF THE DIFFUSION COEFFICIENT

Le Bihan et al. were the first to propose the temperature dependence of the diffusion coefficient as a viable in vivo scale, pointing out that its theoretical sensitivity is usefully larger (at 2.2% °C⁻¹) than that of T_1 .² The relationships they exploited are simple. Data from the sequences (A and B) with differing degrees of diffusion weighting (b) are used. If, as before, the signals for these are S_A and S_B respectively, and the diffusion weightings are, respectively, b_A and b_B then, in more complete form:

$$\frac{S_B}{S_A} = \frac{M_B \left(1 - \exp\left(-\frac{TR}{T_{1B}}\right)\right) \exp\left(-\frac{TE}{T_{2B}} - b_B D(T_B)\right)}{M_A \left(1 - \exp\left(-\frac{TR}{T_{1A}}\right)\right) \exp\left(-\frac{TE}{T_{2A}} - b_A D(T_B)\right)} \quad (6)$$

where $D(T)$ is the diffusion coefficient at the temperature at which the measurements were acquired. From this, b is given by:

$$b = \gamma^2 G^2 \delta^2 \left(\frac{\Delta}{3} - \delta\right) \quad (7)$$

where γ is the gyromagnetic ratio, G is the gradient strength in each of two identical pulses of effective duration δ and having their leading edges Δ apart in time, using the classic pulsed gradient spin echo (PGSE) experiment of Stejskal and Tanner.¹⁶ If both data acquisitions are made at substantially the same temperature (as described in Cline et al.¹³) then Equation (6) can be simplified to:

$$\frac{S_B}{S_A} = \exp(D(T)(b_A - b_B)) \quad (8)$$

In vivo applications of the use of diffusion weighting to monitor temperature are few and far between,^{9,17} though the implementation now of echo planar imaging (EPI)¹⁸ in many machines may change that. Diffusion experiments are notoriously vulnerable to motion artifact, and rapid acquisition of data is highly desirable. As with T_1 , phantom and in vitro data yield very good calibrations of D versus T .

Unfortunately, it is probable that some of the problems noted in connection with T_1 measurement will also affect diffusion-weighted studies. Diffusion in tissue is anisotropic;¹⁹ as a result, the changes in edema and/or perfusion already noted will cause variations in the observed value of D that are not necessarily related to temperature at all. It is possible that calculating the full diffusion tensor²⁰ may allow variations caused

by temperature change to be sorted out from those resulting from tissue structure alterations, but this has yet to be demonstrated, and, at best, will require more images (12, in two sets of 6 at least) to be obtained at each temperature.

6 TEMPERATURE DEPENDENCE OF THE CHEMICAL SHIFT OF WATER

Hindman first demonstrated, and characterized, the chemical shift of water as a means of measuring its temperature.²¹ He suggested that the small effect he observed (of the order of -0.0108 ppm °C⁻¹) was the result of temperature dependence of the shielding constant of the electrons in the water molecule. He based his analysis on the relationship:

$$\sigma_i = \sigma_o + \sigma_d + \sigma_a + \sigma_F \quad (9)$$

where σ_i is the total shielding constant, σ_o is the intramolecular shielding constant for an atom in an isolated molecule, σ_d is the bulk diamagnetic susceptibility component, σ_a is shielding caused by anisotropy in the susceptibility of neighboring molecules, and σ_F is the contribution to the shielding by local electric field effects. Some of these component contributions are temperature sensitive.²¹

This phenomenon was ignored in human MR terms until Ishihara et al. revived interest in it.²² Since then it has been exploited in two quite different ways: through imaging and through spectroscopy. These will be discussed separately below.

6.1 Approaches Using MRI to Exploit the Temperature Dependence of the Chemical Shift of Water

The method Ishihara et al. proposed involved observing the phase differences in the image data as the temperature varied.²² The experiment is a gradient recalled echo (GRE) system in which TE (the echo time) is extended to obtain the necessary sensitivity for the desired temperature scale. If $\omega(T)$ is the temperature-dependent resonant frequency of the water, the phase difference developed between the signals at two different temperatures, ($\Delta\varphi_T$), assuming nothing else is changed, is:

$$\Delta\varphi_T = (\omega T_B - T_A)TE = k(T_B - T_A) \quad (10)$$

where k is the phase coefficient of temperature for the sequence and field used.

If the aim is a measurement accuracy of 0.5°C, then the desirable phase shift sensitivity should be no less than perhaps 30°C per 360° of phase if the phase noise is in the range 3–4°. Even in a 1.5 T magnet (remembering that $\omega = \gamma B_o$) this means that TE has to be around 48 ms. The practicality of the method has been demonstrated at a variety of fields, including as low as 0.2 T,²³ but it is, at the least, a technique that makes substantial demands on machine performance.

A major issue is the possibility of susceptibility effects, which can arise from the tissue itself or as artifacts from neighboring objects.²⁴ A very small susceptibility difference indeed is sufficient to cause substantial errors. If $\Delta\psi$ is an effective susceptibility change that develops, then the phase error caused by it is:

$$\Delta\varphi_s = \gamma\Delta\psi B_0 TE \quad (11)$$

De Poorter et al. were concerned about the nature of possible chemical shift-like changes in lipid-rich tissue as well as in water-based ones,²⁵ but, in practice, effects in fatty tissues seem to be minimal and, indeed, as will be described in the next section, can even be used as a reference.

Since the effects sought are so small, correction for various machine drifts is normally essential.²⁶ This can be done by a variety of methods but involves at least one means of monitoring any drift in the B_0 field. This can be done by phantoms, the temperature of which is controlled, or, in principle, by other methods.

Figure 2 is a phase map typical of those obtained during temperature measurement experiments. The image shows a volunteer's calf muscle during cooling by water pads, which can be seen on either side of the leg. These appear black since, in the image, calculated from an initial data set obtained prior to cooling and one taken as the leg temperature was dropped, the

temperature of the water in the pads is much lower than it was at the start of the experiment. The phantoms used to enable corrections for field drift to be made are apparent round the leg. They are insulated from the cooling pads, and the temperatures of two of them were monitored. The fat in the tissue retains the mid-gray color indicative of no phase change, while the muscle near the pads inside it is colder than it was at the start.

The data in Figure 2 were generated using a protocol involving stabilization of the leg temperature at around 37°C for 30–40 min followed by a rapid reduction in the temperature demand for the water in the pads to 5°C. This command was followed by the water temperature with some delay; consequently when the temperature was reset to 37°C again, typically after 1 h, it had reached a minimum temperature of perhaps 10°C. After resetting, the leg was monitored for a further 40 min. Optical probes on the phantom, on the surface of the skin, and implanted in the muscle under the pads to a depth of 15 mm were used to monitor temperature (Luxtron 3000, Luxtron Inc., Santa Clara, CA, USA).

Figure 2 Image of a phase map of a leg of a volunteer during cooling. The phantoms and fat retain the mid-gray tone indicative of a very small change in phase, while the water pads (seen outside the leg) are very black, as the water is very cold. The muscle temperature has been reduced to some degree. (Reproduced with permission from Young et al., *Magn. Reson. Med.*, 1994, **36**, 369.)

Figure 3 The effect of temperature cycling in a volunteer's calf muscle. Data were obtained from directly under a cooling pad, in the muscle (□) and at the top of the leg in muscle but not directly cooled (●). (a) Chemical shift of water versus temperature; note the hysteresis observable in these data. (b) Proton density values at changing temperature. (Reproduced with permission from Young et al., *Magn. Reson. Med.*, 1994, **36**, 372.)

This temperature cycling produced results of which those shown in Figure 3 are typical. Data from two points are shown: one under one of the pads, and the other at the top of the leg away from any direct cooling. Two pairs of curves are shown, those in Figure 3a being the chemical shift data, while Figure 3b shows proton density data analogous to that shown in Figure 1. It is apparent that the data from the point under the pads both show an unexpectedly large change in phase (as the likely expected change at 1 T with a TE of 60 ms was about $9.3^\circ \text{ phase } ^\circ\text{C}^{-1}$) and also reveals marked hysteresis. The proton density data from the same region also shows substantial changes, and hysteresis. Both sets of data from the other point are much more convincing. Because of suspicions about possible changes in the blood content of the tissue as the body responded to the cooling, it was thought that such changes could have been caused by susceptibility differences,²⁶ though later data (see below) suggests this may well not be correct. The hysteresis effects in the chemical shift phase data are not easy to explain if this factor is excluded; however it seems likely that it will involve changes in the lipid content of the voxels owing to physical movements and composition changes arising as the tissue swells. Since the chemical shift of lipids is around 3.5 ppm relative to water, first sight suggests that small alterations only are needed to explain errors in a measurement where the scale is $-0.0108 \text{ ppm } ^\circ\text{C}^{-1}$.

However, though the scale differences are dramatic, the worst case occurs when the lipid and water components are out

of phase by 90 or 270° , and the many Hertz differences between the two resonant frequencies cannot cause larger errors than those angular differences allow.

If the fraction of lipid components in a voxel is initially δ_A and ultimately δ_B at the same time as the temperature changed from T_A to T_B , at which values the observed phase differences (relative to a starting reference value) were φ_A and φ_B and TE was such that the lipid component was initially 90° out of phase with the water signal, then

$$\varphi_A - \varphi_B = \frac{(1 - \delta_B)\sin kT_B + \delta_B\sin \alpha}{(1 - \delta_B)\cos kT_A + \delta_B\sin \alpha} - \frac{(1 - \delta_A)\sin kT_A + \delta_A\sin \alpha}{(1 - \delta_A)\cos kT_A + \delta_A\sin \alpha} \quad (12)$$

which simplifies to:

$$\varphi_A - \varphi_B = (k(T_B - T_A) + \frac{\delta_B - \delta_A}{(1 - \delta_B)(1 - \delta_A)}) \quad (13)$$

if it is assumed that kT_A and the δ values are small; α is the phase angle difference between the two components determined by the sequence.

Equation (13) suggests that the involvement of lipid changes cannot be the only, or even, it is likely, the dominant cause of the calibration errors observed. The fractional change in the

value of δ would need to be too large for this, for example a 1% change in δ (from 4 to 5%) would result in a change of perhaps 0.6° of phase. At this time, the phenomena seen in Figure 3a have no convincing explanation.

While the true accuracy of the chemical shift method in vivo may not be as good as the many phantom experiments using it have suggested, nevertheless it is a reliable indicator of larger temperature changes and is being studied by a number of groups to this end.^{27,28}

6.2 Chemical Shift Temperature Measurements Using MRS

Cady et al. were the first to suggest using the chemical shift of water to measure temperature in vivo using spectroscopic rather than imaging methods.²⁹ They exploited earlier in vitro data which showed that many metabolites other than water had no temperature coefficient of chemical shift;³⁰ as a result, their signals could be used as internal references in human studies. If there was to be susceptibility, or small main field alterations, this would affect the reference moieties as well as the water, and any differences in the chemical shift of the latter could be readily assigned to temperature changes.

While Cady et al. were interested in measuring the temperature of the neonatal brain during hypothermia to stabilize infants who had been seriously brain damaged at birth,²⁹ the data to be described here were obtained from volunteer calf muscle using the same kind of protocol as described previously.³¹

Typical examples of the data obtained from the spectroscopic studies are shown in Figure 4. Figure 4a shows a typical spectrum and illustrates some of the problems with the

method. Since the water peak is essential for the measurement and since its phase and chemical shift are key issues, it cannot be suppressed, and TE has to be long enough to allow it to be very substantially attenuated relative to the signals of any long T_2 moieties that might act as a reference (or source of comparison). This attenuation has to be sufficient for the dynamic range of the data to be less than that of the receiver system in the spectrometer, with inevitable attenuation of other signals and a relatively poor signal-to-noise ratio. In spite of these problems, performance is good enough for the results shown in Figure 4b to be obtained. This shows data from several other moieties, creatine, choline and lipid (a number of partly resolved peaks treated as a single entity), as well as water. Analysis by Young et al. shows that these components are really very stable, suggesting that susceptibility changes were not a factor in this instance and that the impact of tissue swelling, which occurred as usual in the experiment from which these data were obtained, was minimal using this strategy.³¹

The data shown in Figure 4 were derived from a voxel 15 mm^3 in size, with a temporal resolution of 7–8 min. In both these respects, it fails the criteria discussed in Section 2. Detailed analysis of imaging data overlapping the spectroscopic region of interest showed the same type of pattern that is illustrated in Figure 3.

Spectroscopy appears, on the basis of relatively skimpy data,^{29,31,32} to have robustness for use as a thermal scale that is lacking in the imaging data. At least partly this is because of the large voxel (with the much greater spatial averaging inherent in its use). It is interesting to speculate on how, and if, the two approaches can be used to support each other to produce data that both are accurate and have adequate temporal and spatial resolutions.

Figure 4 Magnetic resonance spectroscopy of temperature changes in a volunteer's calf muscle. (a) Spectrum obtained in the study. The small amplitude of the creatine and choline peaks relative to the water and lipid one is very obvious. (b) Plots of the chemical shift of a number of moieties against temperature. The continuous line is the chemical shift that might be expected from modeling the temperatures to be expected in the tissue using the thermoheat Equation (15), then assuming that the temperature coefficient of chemical shift of muscle is the same as that of water. The chemical shift change for water (●) is derived from the data. The minimal chemical shift of the creatine (■), choline (□) and lipid (▲) peaks versus temperature is very apparent. (Reproduced with permission from Young et al., *JMRI*, 1998, **8**, 1116, 1117.)

7 VARIATIONS IN T_1 OF NUCLEI OTHER THAN HYDROGEN

Many components, such as the chemical shift of methyl groups in complex molecules including paramagnetic nuclei, vary with temperature, and suggestions have been made as to their utility for temperature measurement.^{33,34} The fluorocarbons also have properties that can be exploited,³⁵ though, in this case, the T_1 s of the fluorocarbon lines are also pH sensitive. The relationship between the various quantities is of the form:

$$1/T_1 = A + B(pH) + CT + D(pH)T \quad (14)$$

where A , B , C , and D are constants for any one spectral line; T is the absolute temperature, and (pH) is the tissue pH. As described by Mason et al., from a spectroscopy experiment, the behavior of the multiple lines can allow the solution of a set of simultaneous equations and resolve the differences between changes caused by temperature and pH.³⁵

As yet none of the methods suggested has been used in vivo.

8 IMAGE PROCESSING

A problem with temperature measurement in vivo, which distinguishes it from any phantom experiment, is that tissue is mobile and responds to thermal stress by a range of potential changes. Without identifying its source, cooling the leg, for example, results in swelling of the tissue. Then, if no action is taken, the tissue content of a region of interest in a voxel determined by the machine gradients, and not adjusted in any way, will change continuously. It is not surprising, therefore, that content variations can result in substantial errors in small voxels, with relatively low signal-to-noise ratio, and be less apparent in the much larger voxels used in spectroscopy.

The extent of the effects is demonstrated in Table 1 (line 1) and the results of the efforts to improve the situation using registration are described by Hajnal et al.,³⁶ while data correction using other strategies is described by Saeed et al.³⁷ The latter includes attempts to track the mean intensity of the voxel by selecting a closest local match to the standard deviation of the original gray-scale voxel. Another variant combined that approach with a best match to distances from a number of landmarks surrounding it.

All the data in Table 1 are from a T_1 experiment, and it is

clear that though substantial image processing can improve matters, it does not transform the situation completely.

9 CONCLUSION

Temperature measurement in vivo using MRI and MRS has become a matter of considerable interest to the scientific community, particularly since the usefulness of interventional MRI has come to be appreciated. It seems unlikely that it will reach the performance target suggested in Section 2 of this article. However, if the temperature target were to be reduced so that the accuracy were to be $\pm 3^\circ\text{C}$, then it is likely that MRI will become of real value as a temperature measurement. This will not allow as much appreciation of the risks, and extent, of collateral damage to normal tissue round a target lesion as is desirable. If this is acceptable clinically, then we can look forward to the increasingly widespread application of direct temperature measurement in interventional MRI.

1 INTRODUCTION

In its short history, MRI has been championed over X-ray techniques as a noninvasive, noninterventional, diagnostic tool that provides exquisite anatomical detail and soft tissue contrast. Ironically, many of the advantages contributing to the diagnostic success of MRI are now being used to expand the role of MRI into the interventional or therapeutic arena (Figure 1).

1.1 Visualization

Much of surgical technique has been developed to provide exposure or visualization of the surgical field. The actual treatment is often a small portion of the entire procedure compared with the surgical steps necessary for visualization.

MRI has the ability to acquire high-contrast, submillimeter resolution detail in two or three dimensions in any orientation. This feature has been used since the mid 1980s to locate and guide biopsies of deep target tissues with limited accessibility. Stereotactic frames with MR visible markers have traditionally been used to register the target location on the MR images with an external reference. The MR image not only provides an accurate location of the target but also demonstrates the relationship of the target to surrounding vital structures including nerves and vessels using MRA techniques. This information is essential to planning the least invasive trajectory for a biopsy or therapeutic device. Although large-scale clinical acceptance of MR-guided biopsy has been slow due to the high cost and inaccessibility of conventional MR units, the reported clinical applications are growing and now include head and neck, brain, prostate, liver, and mediastinum.¹⁻⁷ One new area that is expected to become a large application for MR-guided procedures is the evaluation of breast lesions detected by MR that are invisible on mammography.

Ultrasound and computerized tomography (CT) have been used in the past to guide biopsy procedures. MR provides soft tissue detail superior to CT and higher spatial resolution than ultrasound. The impact of MR guidance on surgical procedures is to reduce both the time required for visualization and the potential for related complications, ultimately improving patient management.

Figure 1 T_2 -weighted fast spin echo image demonstrating MR-compatible rf therapy probe placed on target in patient with metastatic brain tumor

1.2 Therapy Monitoring

While facilitated visualization is a key aspect of improving an interventional procedure, MR is uniquely qualified to participate in the therapeutic process itself. Once the probe has been placed on target and the therapy administered, MR imaging can demonstrate thermal changes as well as tissue characteristics secondary to the treatment. Sequential MR acquisition, coupled with image subtraction and display in the examination room, provide an environment in which the therapy session becomes an iterative process. Projects are currently underway to develop accurate and reproducible methods of thermal dosimetry using MR, providing the physician with feedback on therapeutic effect during the procedure.⁸

2 BASIC PRINCIPLES OF MR THERAPY MONITORING

Any imaging technique, by definition, makes use of physical differences between neighboring tissues to create a visual map of tissue interfaces (e.g. density in CT, acoustic impedance in ultrasound, uptake of radioisotope in nuclear medicine, etc.). The MRI signal depends on the structure and dynamics of water-macromolecular interactions. Since these interactions are affected by energy absorption, the MRI technique provides a means of visualizing therapeutic administration.

2.1 T_1 Temperature Monitoring

As a tissue is heated, the distribution and mobility of water and lipid molecules change. These changes alter the tissue relaxation times, T_1 and T_2 . T_1 dependence on temperature can be exploited to detect temperature changes during and after therapy using MRI⁹ (Figures 2 and 3).

Figure 2 Series of time-lapsed T_1 -weighted MR images acquired before (a), every 25 s during (b)–(j), and after (k)–(p) laser irradiation of sheep brain in vitro. Open arrow designates tip of laser fiber optic and bold arrow shows temperature probe 1.5 cm from laser

2.2 T_2 Edema Monitoring

In a typical thermal ablation procedure, the tissue temperature is raised to 60–80°C in order to produce protein denaturation and coagulation necrosis. Tissue changes associated with these processes are detectable using T_2 -weighted MRI. Basic animal studies have characterized the acute tissue effects of laser heating, for example, and their MR appearances.¹⁰ In addition to a high sensitivity to edema, T_2 -weighted images reveal a clear-cut MR appearance of thermal-induced lesions: concentric rings which closely reflect the actual pathologic changes of central cavitation, coagulation necrosis, and tissue edema (Figures 4 and 5).

Figure 3 Relationship between temperature (T) and T_1 signal intensity (S) during and after laser irradiation

Figure 4 T_2 -weighted images of a laser-induced lesion in an animal model immediately after laser exposure (a) and up to 40 min later (f). Note the expansion of the lesion (arrow)

Although the regions of cavitation and coagulation necrosis clearly represent irreversible cell damage and death, the ultimate disposition of the edema layer is important in the quantification of the tissue damage. Preliminary data from chronic studies in animal models suggest that the area of cell death may expand up to 44% into the edema region depending on a number of factors as the healing process occurs.¹¹

2.3 Position Monitoring

While most of the new developments in interventional MR involve therapy monitoring, there is also a need for

Figure 5 Gross pathology of the laser-induced lesion showing concentric regions of cavity, coagulation necrosis, and edema

Figure 6 Simulation of real-time position tracking of catheter using an MR angiography road-map, real-time MR scanning and an rf-based tracking system

real-time position tracking of therapeutic instruments. Techniques are under development that will allow tracking of invasive devices (e.g. catheter) in real time using magnetic resonance.¹² By incorporating one or more small rf coils into a device, MR signals will be detected only from excited tissue in the immediate vicinity of the device. An MR pulse sequence using only read-out gradient pulses can localize the position of the receiver coil in the direction of the applied gradient. Repeating this technique in three orthogonal directions permits localization of the rf coil in three dimensions. Such a sequence can be repeated rapidly to provide position information in real time. This position information can be superimposed on a prospectively acquired anatomical 'road-map' (Figure 6). This technology may prove instrumental in making a field such as interventional MR angiography a reality.

3 THERAPEUTIC TECHNIQUES AND CLINICAL APPLICATIONS

Techniques of interstitial therapy can be separated into two mechanistic categories: chemical and thermal.

3.1 Chemoablation

Various strategies for chemoablation under imaging guidance have been used for years in angiography and other areas of classical (endovascular) interventional radiology. Many of these approaches will have applications interstitially as well. For example, injection of ethanol into tissues in sufficiently high concentration will result in local dehydration necrosis. Animal studies confirm the ability of MR to demonstrate lesion size and shape.¹³ Initial human studies have been reported in liver applications.¹⁴

3.2 Thermal Ablation

Manipulation of temperature can cause tissue destruction either by freezing and cell lysis at low temperature or protein denaturation at high temperature. Hyperthermia, tissue heating to temperatures in the range of 43–45 °C, can sustain sublethal injury that becomes irreversible after extended exposure, depending on the type of tissue and experimental or therapeutic conditions.

Thermal ablation at higher temperatures (60–90 °C) is more useful for MR-guided therapeutic purposes because it is quicker to deliver. Unlike alcohol injection, which follows fascial planes, thermal ablation results in an ellipsoidal area of tissue destruction, depending on local thermal conductivity. Neighboring vessels, for example, can act as heat sinks, decreasing the heating effect on surrounding tissues.

There are two main techniques currently being used clinically for administering thermal interstitial therapy: laser ablation and radiofrequency ablation. In addition, a new technique using focused ultrasound is currently under investigation.

3.2.1 Laser Ablation

This technique involves a fiber-optic-laser delivery system such as a neodymium–yttrium-aluminum-garnet (Nd:YAG) laser placed interstitially. The technique has been used in the past for treatment of hepatic tumors and head and neck lesions.^{15,16} Since the absorption coefficient of laser energy is variable, depending on the tissue characteristics, the prediction of tissue volume that will be coagulated with a given power output or exposure time setting is difficult in the clinical setting without a monitoring technique such as MRI. Laser therapy is well suited for MR guidance since fiber optic probes are MR-compatible.

Laser-induced lesions show the characteristic zonal segmentation described earlier: cavitation, coagulative necrosis, and edema. In a study of laser lesions in muscle tissue of an animal model, the area of coagulative necrosis resulting from laser irradiation increased in size up to 7 days posttreatment. Progressive resolution resulted in absorption of injured tissue and subsequent replacement with fibrous scar tissue.¹¹ MRI findings correlated well with pathologic findings in this chronic model.

3.2.2 Radiofrequency Ablation

A radiofrequency probe may also be used to produce tissue destruction by means of remote heating. Applications of this technique using MR monitoring were made possible with the development of MR-compatible rf-generating systems and probes.¹⁷

By defining rf dose based on temperature exposure in seconds (e.g. 80 °C for 60 s), lesions created using radiofrequency ablation can be more accurately controlled. Using a thermocouple to monitor tissue temperature adjacent to the rf probe during ablation, MR images are acquired to assess acute tissue changes secondary to rf therapy.

A clinical series involving treatment of primary and metastatic brain tumors using MR-guided rf ablation is currently underway with a 12 month follow-up completed^{18,19} (Figure 7). Patients are treated under MR guidance with local anesthetic, accessing the brain through a 2 mm-twist drill hole

Figure 7 Serial postcontrast MR images of a patient treated with MR-guided rf ablation of a metastatic adenocarcinoma to the brain. The images were acquired (a) immediately following rf ablation, (b) 1 week, (c) 1 month, and (d) 5 months posttreatment

instead of an open craniotomy (Figure 1). Since the patients are awake and communicating with the physician, neurological symptoms can be monitored during the entire procedure, a significant advantage over open craniotomy procedures requiring general anesthesia. The procedure may be done as part of a biopsy procedure and can be used in previously fully radiated patients and/or in instances of recurrence. These types of interventional MR procedures are ideal for patients who are elderly and/or have systemic diseases that preclude the option of general surgery.

3.2.3 Focused Ultrasound Ablation

New techniques in which focused high-power ultrasound beams are used to create tissue necrosis under MRI guidance are being investigated.^{20,21} This technique is capable of creating focal lesions in deep tissues which are clearly depicted by MRI, particularly using T_2 -weighted sequences (Figure 8). Although this approach has the distinct advantage of not requiring a needle, catheter, or any direct skin violation, it does require an ultrasonic path to the lesion (i.e. a path free of air and bone). Projects are underway to develop an MR-compatible, focused, ultrasound hyperthermia system to improve the clinical utility of this technique.

4 SPECIALIZED EQUIPMENT

4.1 MR-Compatible Instruments

The first step toward practical interventional MRI was the development of satisfactory instruments that could be used in the high magnetic field necessary for clinical MRI. Even 'low'-field MRI systems produce significant untoward effects on many standard interventional instruments.

Instruments made from ferromagnetic metals result in geometric distortions of the image causing large artifacts. A more dangerous effect of many of these metals is the tendency for them to experience torque and be accelerated in the magnetic field, thus risking damage to patients and imaging team personnel. By substituting high nickel content stainless steel or other nonferrous materials, researchers have developed new MRI-compatible instruments at reasonable costs.^{1,17} These devices are safer for the patient and imaging

Figure 9 (a) MR-compatible rf therapy probes (Radionics, Inc.), (b) susceptibility artifact caused by stainless steel biopsy needle, (c) reduced artifact from MR-compatible needle (E-Z-EM, Inc)

team personnel and result in reduced artifacts relative to standard instruments (Figure 9).

4.2 Open MR Systems

In 1993, the first of a new generation of MR scanners specifically designed for MR-guided interventional procedures was introduced (Figure 10). An interventional magnet must have open patient access, flexible patient positioning, and open rf coil designs that provide sufficient image quality for MR therapy monitoring without impeding therapeutic access.

4.3 Advanced Localization and Display Systems

Although very accurate and reliable, frame-base stereotactic techniques are uncomfortable and invasive. The development of powerful new frameless localization systems using articulated arms and optic sensors are enhancing the impact of MR guidance on minimally invasive surgical procedures, improving efficiency and patient acceptance (Figure 11). These devices obviate the need for stereotactic frames that fit inside rf coils, opening up more applications of interventional MR.

The MRI scanning paradigm used over the last decade in which the technologist stands outside the scanner room and

Figure 10 An example of one of a new generation of MR instruments specifically designed for interventional procedures. This system is from Siemens and operates at 0.2 T

Figure 11 Operating Arm System™ (Radionics/RSA, Inc.) allows registration of the surgical field to three-dimensional MR data. Ultimately, the physician will be able to define scan plane orientation and initiate acquisition interactively during the interventional procedure

obtains images on a console is currently being rethought with interventional MR. Rapid three-dimensional segmentation and rendering of patient image information is necessary for treatment planning and monitoring during the procedure. Image subtraction, dosimetry modeling, and calculation routines are necessary for proper treatment administration and should be displayed in the MR scan room. In addition, the need for interactive scan plan definition and sequence selection is required in the MR scan room to improve efficiency of the therapeutic procedure. New interventional MR workstations with powerful graphics capabilities are currently under development to address these issues.

5 FUTURE DIRECTIONS

Interventional MR is clearly in its early stages of development. With dedicated interventional MR units now available and sophisticated workstations under development, the next step is to identify clear-cut clinical indications and begin large clinical trials to define the ultimate value of interventional MR.

Even with current technology, it is possible to imagine dedicated MR therapy units for combined radiological and surgical approaches in what may be the archetype for operating rooms of the 21st century.

Thermal Therapies in the Body Monitored by MRI

Margaret A. Hall-Craggs, S. Smart, and A. Gillams

The Middlesex Hospital, UCLH, London, UK

1 INTRODUCTION

The purpose of minimally invasive therapy (MIT) is to deliver effective treatment with the minimum disruption and damage to normal surrounding tissue. Consequently the morbidity of the procedure may be reduced compared with an open operation. Measures of this may be such factors as reduced scarring and deformity (as in the breast), more rapid postprocedural recovery, and reduced hospital stay (as in intra-abdominal procedures). In some cases, therapy may be used where there is no other treatment option, as in tumor metastases to multiple lobes in the liver.

Treatment using MIT is fundamentally different in benign and malignant disease. In benign disease, total eradication of the target tissue may not be necessary and size reduction may be adequate. This is the case with breast fibroadenomata and also in uterine fibroid disease where amelioration of menorrhagia or infertility is the treatment aim. With malignant disease, surgical principles preside; in general, tumor resection/destruction with an adequate margin is the treatment aim. Further MIT must not impose additional risks such as increasing the rate of local recurrence or distant disease spread, or reducing disease survival.

A host of MIT techniques have been developed since the mid-1970s; these include the thermal ablative techniques to be discussed in this chapter. Other are percutaneous excision, photodynamic therapy, interstitial radiotherapy/brachytherapy, chemical ablations, laparoscopic surgery, lithotripsy, and intraluminal/intravascular procedures such as stenting, embolization, dilatation, etc.

2 METHODS OF THERMAL ABLATION

There are four principal methods of thermal ablation. Three of these involve heating of the sample—interstitial laser photocoagulation (ILP), radiofrequency (rf)-induced coagulation (RFC) and focused ultrasound (FUS)—while the fourth, cryoablation, uses cooling.

2.1 Interstitial Laser Photocoagulation

For ILP, fiber optic cables that emit light only from their tips are placed into the target region. These are coupled to a laser source and the light is turned on for the duration of the treatment. Theoretically the frequency of the light has to match an absorption band of some (unspecified) chromophore within

the target region so the light energy can be converted into heat. There have been a number of approaches to improving the coupling of light to the tissue and these include the use of a focusing lens at the fiber tip and diffuser tip fibers. However it appears that laser energy deposition is primarily a thermal process. Pre-charring the optical fiber causes the fiber to behave as a point heat source (paradoxically reducing light transmission) and increases the size of the laser burn.¹ The use of low laser powers (<5W) allows the slow and controlled development of lesions over extended periods (300–1000s).

In our practice, we have used the semiconductor diode laser as it offers a number of advantages. It is small, compact, and easily transportable; it does not require a cooling system and operates from a conventional phase electrical source.

2.2 Radiofrequency

RFC uses rf alternating current source applied through needles tipped with rf electrodes. Frictional heating is induced via ionic agitation arising from the impedance of the tissue to alternating currents. The rf source typically operates at up to 500 kHz and will often interfere with the MR acquisition at all field strengths. Such interference with the MR measurement can be reduced or eliminated with an appropriate choice of electronic filters, or by gating the rf source off during MR signal reception. This latter approach can easily be performed by simple modification of pulse sequence code. To complete the electric circuit for the applied AC, grounding pads must be applied to the patient. Care must be taken with these to prevent the possibility of local skin burns at the site of the pads. RFC can form lesions faster than ILP; however, because the deposition of the heat depends upon the electrical characteristics of the tissue, the formation of the lesion may be inhomogeneous, especially in regions of tissue boundaries.

2.3 Focused Ultrasound

FUS uses an array of ultrasound sources, typically operating at 1.5 MHz, the energy of which converges at a focus within the body. In this region, a significant amount of acoustic energy is converted into heat. The volume of the hyperthermia is very well defined for FUS; as a result, a sharp boundary may be observed between normothermic regions and those bound for necrosis. The duration of the treatment depends upon the ultrasound parameters but is typically in the region of tens of minutes. Lesions as small as 1 mm³ can be created; consequently, high-resolution imaging techniques, such as MRI, are necessary for their accurate detection and monitoring.

2.4 Cryotherapy

Cryosurgery will typically involve the use of a needle that is continuously cooled by liquid nitrogen and which is insulated along the length of its shaft except for at the tip. The tip of the needle acts as a heat sink for the tissue and so acts as a point source for cooling. Thermal conduction increases the volume of cooled tissue. There are a variety of mechanisms responsible for the subsequent necrosis, and these depend upon the organ undergoing the cryosurgery. As for FUS, there is a well-defined boundary between normal and treated tissues.

3 ROLE OF IMAGING IN THERMAL ABLATION

The principal roles of imaging in ablative treatments are to define the extent of disease, to guide instruments, to monitor treatment during the therapeutic procedure, and to show the effect of therapy. In practice, a combination of imaging modalities are used to achieve these aims, including computed tomography (CT), ultrasound, and MR. However, there are a number of specific properties that have made MR the subject of much research interest. The exploitation of temperature-sensitive sequences can potentially be used to map areas of tissue damage during an ablative procedure, and this may facilitate treatment modification at the time of delivery to improve efficacy. Other advantages include multiplanar imaging, which facilitates the guidance and accurate placement of tools. The lack of ionizing radiation is of importance to both the patient and the operator with lengthy therapeutic procedures.

4 MAGNET AND EQUIPMENT CONSIDERATIONS

Interventional procedures have been described both in conventional tubular high-field systems and in lower-field magnets designed to have more open access. In open systems, the tissue of interest can be located within the 'active volume' of the magnet for MRI, and the surgeon may have access to this volume from several sides. The use of the more conventional tubular high-field magnets is hindered by limited bore diameter, which limits the size of interventional devices, and by the restricted access owing to the magnet length, which prevents realtime MR-monitored adjustments of interventional tool position. On open access systems, rapidly and dynamically acquired MRI scans can assist with the positioning of interventional devices. Fast MRI may also allow near realtime visualization of physical changes within the tissue during interventional procedures. Typical procedures include MR-guided biopsies, tissue excisions, and thermal ablations. In this article we shall describe aspects of thermal ablation treatment in the human body as monitored by MRI.

All interventional devices located within the region of treatment must be made of MR-compatible materials. Such tools are available and are usually made of alloys or ceramics that present a low magnetic susceptibility difference to the body. However residual susceptibility artifacts, dependent upon the applied magnetic field strength and on the orientation of B_0 relative to the interventional device, persist and may compromise image quality in their locale, especially when using gradient echo methods. The materials used in the manufacture of these MR-compatible devices are often soft, too flexible, and are difficult to tool to sharp and cutting tips. They are also expensive.

For ILP therapy it is possible to use MR-compatible needles to position the optical fibers and then to withdraw the needles leaving the fiber in place; this eliminates the susceptibility problem. For RFC and cryotherapy, the needles must remain in place; consequently susceptibility artifacts are unavoidable. This is not necessarily a severe problem for FUS as the sonic transducers are positioned around the body not within the target region of tissue.

5 MR METHODOLOGY

Fast imaging methods are required for interventional therapies to facilitate tool guidance and to monitor therapy. Long scan times are also precluded by gross patient motion arising from respiration or peristalsis. The use of navigator echoes may allow the correction of some but not all of these motions. Prospective ordering of the phase-encode steps (e.g., respiratory ordered phase encoding, ROPE) can reduce the degree of motion artifact but requires good calibration and is sensitive to any respiratory irregularity. The use of breath-holding, especially when controlled under general anesthesia, allows imaging free of motion artifacts for scan times of up to about 30 s.

Open-access scanners tend to operate at lower field strengths than those used for routine clinical imaging and this reduces the possible signal-to-noise ratio (SNR). The rf and gradient hardware of the open-access scanner also tends to be of lower specification than that of a high-field research-grade scanner. Some fast imaging protocols, e.g., echo planar imaging, may, therefore, not be available. Further the inherently low SNR realistically achievable with low-field scanners and the persistence of susceptibility artifacts, arising from interventional tools, may make echo planar imaging impractical for some of these applications.

Rapid image reconstruction and display is necessary for realtime monitoring. This may be achieved more quickly by by-passing the scanner and using custom built hardware and software. Methods such as keyhole imaging and local-look scanning have also been used to enhance image update rates.

5.1 Sources of Contrast for Monitoring Thermal Ablations

Successful monitoring of hyperthermic ablations requires a temperature-dependent source of contrast for the heated region. It is important that any contrast seen is a direct consequence of the heating effect rather than resulting from a subsequent effect such as coagulation. Most successful studies demonstrating realtime monitoring of the effects of temperature in thermal ablations have, to date, been performed in model systems and generally using high-field systems. Currently favored mechanisms of temperature-dependent contrasts are T_1 based, where a focal change in the signal amplitude is seen when running under conditions of partial saturation, and proton resonance frequency, where changes in the signal phase with temperature are seen. The proton resonance frequency method is essentially a chemical shift effect and so is most successful at high field. Molecular diffusion has also been proposed as a method for introducing temperature-dependent contrast. However, this method has not been used widely as it is extremely sensitive to bulk patient motion, and because of the potential for anisotropic diffusion to introduce orientation-dependent contrast.

For cryogenic ablations, rapid and accurate monitoring of the region of treatment is possible. As the tissue water solidifies, its T_2 time is greatly reduced; as a result, no echo signal can be measured using conventional MRI hardware. The border of frozen and unfrozen tissues is extremely well defined and for situations where multiple cooling probes are used, any pockets of normothermy can be readily identified allowing repositioning of probes to encompass a given volume of interest. However, direct and unequivocal MR thermometry is

precluded, at all field strengths, by the absence of signal from those regions that are frozen.

6 MR-MONITORED THERMAL ABLATION PROCEDURES

6.1 Interstitial Laser Photocoagulation in Breast Disease

Most work has been performed using the semiconductor diode laser (805 nm) and Nd:Yag (1064 nm) pulse lasers.²⁻⁵ Studies have shown that a power of 2–2.5 W applied for about 500 s will generate lesions of up to 10 mm. Lesion size and reproducibility can be improved by pre-charring the fiber. Larger burns (of up to 40 mm) can be generated by using multiple fibers or pull-back techniques. In a dose escalation study, Akimov has shown that at higher power (over 3 W), tumor vaporization can lead to tissue explosions.⁴

In most studies, patients are treated with local anesthesia and sedation alone; general anesthesia is unnecessary.

6.1.1 Benign Breast Tumors

In our institution we have treated just under 50 benign fibroadenomas of the breast with ILP. Diagnosis is made before treatment by triple assessment and either cytology (C2) or core biopsy. Lesions of up to 4 cm diameter have been treated with between one and four fibers at 2–2.5 W (1000–4000 J). Follow-up for at least 1 year by clinical and ultrasound examination is available in 14 of these patients; in each case the mass has become impalpable by 1 year. In 13 patients, the tumor could not be seen on ultrasound by 12 months' follow-up and in the remainder a 9 mm remnant persisted.⁶

MR has a very limited role to play in the monitoring of ILP therapy to benign tumors. Fibroadenomas have variable enhancement characteristics; some enhance very intensely and others not at all. Consequently contrast-enhanced MR is not of consistent value. Those lesions that do enhance before treatment show areas of devascularization after treatment, but this is not of any clear clinical value. Ultrasound is a quick method of localizing needles within lesions and the treatment parameters are relatively standard. Unlike malignant disease, the treatment of margins is not critical; therefore, accurate monitoring of therapy is not essential.

6.1.2 Breast Cancer

All studies have reported that ILP can cause cell necrosis in breast cancers.³⁻⁵ Treatment of small relatively spherical tumors can be complete. Treatment of larger lesions is more challenging as modeling the treatment area to conform with irregular large masses and ensuring treated margins is much more difficult.

Most studies have examined ILP where treatment has been followed by early surgical excision of the tumor and there are very few long-term follow-up data. There are small numbers reported where ILP has been the sole method of treatment. Akimov treated seven women with ILP alone. Two of these died of other causes and without tumor recurrence; a third had disease-free survival of over 5 years. In our own recent experience in a cohort of selected elderly women who are undergoing ILP and delayed excision at 3 months, we have

been able to show complete tumor ablation sustained over the 3-month period in small numbers.

Complete tumor ablation and treatment of an adequate margin is essential in the management of breast cancer. The surgical literature has shown that incomplete tumor excision is a major risk factor for local tumor recurrence. Yet it is the margins that are most difficult to treat with ILP because, when the fiber is placed in the center of a lesion, the periphery does not reach as high a temperature as the center of the tumor. In one patient treated with ILP alone, Akimov has shown peripheral tumor recurrence. We have found that when there is inadequate tumor ablation, viable cells are invariably found around the periphery of the mass. Unless margins can be reliably and consistently treated, ILP cannot be accepted as a reasonable form of primary therapy in breast cancer.

Contrast-enhanced MR imaging has an essential role to play before therapy to map accurately the extent of the tumor and thus facilitate appropriate case selection. Treatment changes can be seen at high field during ILP using T_1 -weighting sequences. Areas of low signal develop around the fiber tip within a minute of treatment starting and these areas broadly correlate with the histologic extent of tumor necrosis.^{3,5} Consequently, MR does appear to have the potential to monitor treatment in close to realtime. Ideally, areas of signal change should be matched to the tumor. This is not easy in practice as the majority of tumors are only visible on contrast-enhanced scans. Repeated use of contrast causes enhancement of normal breast parenchyma and the loss of contrast between normal and abnormal breast tissue.

Following treatment, delayed contrast-enhanced MR can be used to show the effects of treatment. Areas of devascularization (nonenhancement) occur within the treated area. Occasionally rim enhancement may occur around an adequately treated lesion as a result of peripheral inflammation.

The only significant complications of ILP reported are collateral burns to skin and muscle. The former can be avoided by irrigating the skin with chilled saline during treatment. Burns to the pectoralis muscle can be avoided by accurate placement of the fiber tip.

6.2 Radiofrequency, Cryotherapy, and Focused Ultrasound in Breast Disease

Experience using these thermal treatments in breast disease is very limited. Preliminary reports of the use of rf *in vivo*⁷ and *in vitro*⁸ have shown that histologically confirmed areas of cell necrosis occur. MR monitoring of rf therapy during treatment is limited by the need to have the metallic probe in position during the procedure. There are limited reports of the use of FUS in breast tumors.^{9,10} Prolonged treatment times reduce patient acceptance of the procedure, and patient movement compromises treatment. Cryotherapy has been shown to produce tissue necrosis in breast cancers¹¹ but no significant clinical studies have been reported.

6.3 Bone and Soft Tissue Tumors

There are limited reports of the application of MIT to bone and soft tissue tumors. ILP and rf are being used routinely in the ablation of benign osteoid osteomas. As the tumors are best

seen on CT and treatment parameters are standard, MRI has no role.

There has been some preliminary experience with the treatment of bone metastases with MIT, but it is difficult to justify these experimental therapies when local radiotherapy is effective, widely available, and well tolerated.

We have limited experience treating soft tissue metastases from soft tissue and bone sarcomas with PDT, rf, and ILP. In these patients (with chemo- and radio-insensitive tumors who have all undergone multiple previous operations), we have had variable results ranging from complete tumor ablation in patients with small volume disease to no effect in patients with massive recurrence.

MR has been useful in these patients to stage local disease and for showing post-treatment changes. For complex tumors, needle placement is facilitated by MR as frequently the tissue/tumor contrast is not sufficient to enable accurate tumor localization with CT guidance.

6.4 Fibroid Disease

ILP and rf have been used to treat uterine fibroids (leiomyomata) percutaneously, endoluminally, and at laparoscopy. The advantage of the last approach is that the peritoneum, which is very susceptible to thermal damage, can be directly visualized. The main role described for MR is in the monitoring of treatment response: fibroids frequently exhibit an iceberg effect and the extent of local damage cannot be accurately assessed by direct visualization. There is no published experience of per-procedural MR guidance to our knowledge.

6.5 MR-Guided Ablation of Liver Tumors

The four principal techniques used to achieve percutaneous hepatic tumor ablation are ILP, RFC, cryotherapy, and percutaneous ethanol injection.

A number of centers including our own are now routinely using rf and ILP to ablate hepatic metastases. In our own center most procedures are performed under local anesthesia and conscious sedation, with approximately 15–20% requiring general anesthesia. The 0.2 T Siemens Viva open-interventional MR system provides good access for either a subcostal or intercostal approach to the right lobe of the liver, or an anterior oblique approach to left lobe lesions with the patient in the supine position. A body flex coil provides adequate coverage of the area of interest and good access for needle positioning. Initial breath-hold T_1 -weighted gradient echo images (repetition time (TR); echo time (TE) 152 ms, 9 ms; flip angle 70°) scans are performed to locate the tumor. If tumor visualization is not adequate on baseline images, then liver-specific contrast agents are given (Figure 1). Either super-paramagnetic iron oxide particles (Ferumoxide, 15 mmol kg^{-1} , Guerbet) or T_1 -shortening manganese-based agents (Mangafodipir trisodium Teslascan, 0.5 ml kg^{-1} , Nycomed Amersham) will provide a long period of enhancement, facilitating tumor visualization. Needle placement can be performed entirely using MR guidance or by using a combination of ultrasound and MR. Generally we have favored the use of ultrasound for speed of needle placement, reserving MR for tumors not easily visualized by ultrasound and for confirmation or finessing of the final needle position. If ultrasound guidance is used, the patient is positioned within the

Figure 1 Coronal section through the liver following Endorem during interstitial laser photocoagulation therapy to a colorectal metastasis. The large tumor is seen as a relatively bright mass in the low signal liver. Two 19 gauge MR-compatible needles are shown positioned within the mass

coil on the MR table, and then the table is undocked and moved across the 5 G line, approximately 2 m from the magnet, to the ultrasound machine.

6.5.1 Needle Visualization

Needle positioning is confirmed using multiplanar, often double-oblique T_1 or T_2 gradient echo images (Figure 1). As needle visualization is reduced when it is aligned with the B_0 field, a direct vertical puncture is best avoided. Other mechanisms for increasing needle visualization include swapping the phase- and frequency-encoding directions. Greater magnetic susceptibility and, therefore, better needle positioning can be achieved with the frequency encode perpendicular to the needle direction. Other techniques include increasing the number of averages of using breath-hold imaging. In practice breath-hold imaging is very difficult to achieve in sedated patients and if general anesthesia is being performed will require the addition of muscle paralysis and intubation.

For laser therapy, up to eight bare-tip fibers are used inserted through 19 G hollow, MR-compatible needles (Cook, Europe). For RFC, MR-compatible single rf electrodes are inserted directly. Where electrode clusters are required, guide needles are used as MR-compatible electrode arrays are still in development.

6.5.2 Monitoring the Treatment

We use a T_1 -weighted fast inversion-recovery sequence (TR, 1068 ms; TE 48 ms; time to inversion, 80 ms; number of signals averaged, 1 in 59 s; collimation, 10 mm; matrix, 182×256) to monitor the changes produced by thermal ablation (Figure 2). On this sequence, untreated tumor is seen as high signal intensity against lower signal intensity liver. Over time, an area of reduced signal intensity develops at the treatment site and becomes progressively lower in signal intensity and larger in size. Around the area of low signal intensity, a high

Figure 2 Transverse short tau inversion recovery images through the liver before (a) and after (b) interstitial laser photocoagulation (ILP) to a hepatic metastasis, showing treatment effect. The high-signal peripheral metastasis shows a low-signal focus within the center of the tumor following 8-fiber ILP to the mass. These changes confirmed a treatment effect but underestimated the changes seen on follow-up contrast-enhanced computed tomography

signal intensity ring of edema is also visualized. Although the area of low signal intensity correlates with the final area of thermal ablation on contrast-enhanced CT at 18 h, in general the MR image underestimates the final extent of necrosis. We perform monitoring scans at 10-min intervals throughout the treatment.

Treatment-sensitive sequences could theoretically provide more accurate monitoring information but are difficult to implement in the liver in vivo. Minimal signal intensity changes requiring image registration and subtraction are inaccurate. The shape of the liver is not constant but changes on respiration. A 13% error in liver registration in the craniocaudal direction has been reported.¹² Further thermal injury itself produces a change in the liver shape and contour. Motion artifact becomes increasingly problematic during treatment when the patient is sedated and unable to breath-hold. Therefore, although ex vivo and animal experimentation suggest that both T_1 contrast and phase frequency shift will provide accurate temperature information^{13–15} both Kettenbach and Vogl report difficulties with susceptibility and motion in vivo.^{16,17} Vogl uses phase frequency shift at 1.5 T with the relatively simple indicator of a 50% reduction in signal to terminate treatment; and this is considered sufficient for tumor ablation by this group.¹⁷

The use of rf suffers from the additional problem of interference with MR image acquisition; as a result, monitoring

sequences are performed at breaks in the treatment cycle. Steiner et al. found good correlation between phase frequency shift imaging at 0.5 T immediately at treatment end and final ablation volume.¹⁵ However, liver cooling is rapid (of the order of 50 s) and, therefore, there is only limited opportunity to acquire the necessary information.

For cryotherapy, MR-compatible cryoprobes have been developed. The iceball is well visualized but tends to underestimate the final lesion size.^{18,19}

Percutaneous ethanol injection, unlike the other ablation techniques, is reserved for the treatment of hepatocellular carcinoma. Although ex vivo experiments have suggested the use of water-suppressed T_2 fast-spin echo images for monitoring the actual injection and animal experiments have suggested that ethanol produces low signal on all sequences, in practice a range of signal intensity changes are produced and MR assessment relies on the absence enhancement during arterial phase imaging to indicate complete ablation.^{20–23}

6.5.3 Long-term Follow-up

Most groups prefer CT for long-term follow-up because of cost and availability.

6.5.4 Conclusions

MR guidance offers improved multiplanar imaging compared with other imaging techniques; although quantitative temperature measurement is not yet a reality, MR does provide some monitoring information.

6.6 MR-Guided Ablation in the Prostate

Failure of traditional treatments and the associated morbidity has driven a multifaceted search for alternative therapies for prostate treatment. There are now a number of image-guided treatment options under evaluation for localized prostate cancer, including cryotherapy, brachytherapy, and photodynamic therapy. Laser therapy has been used in benign prostatic hyperplasia. Fluoroscopy, CT and transrectal ultrasound have all been used to guide prostatic interventions. Of these, CT and fluoroscopy provide no information about the internal architecture of the prostate and are unidimensional; transrectal ultrasound offers significant detail of the internal prostatic architecture but does not show the needle trajectory from perineum to prostate. In addition, the presence of the probe in the rectum holds the rectal wall against the prostate gland. MR offers multiplanar imaging, any plane, any obliquity, good prostate detail, and images of the full needle trajectory and of neighboring structures without distortion of the anatomy.

6.6.1 Photodynamic Therapy in the Prostate

We have used interventional MR to guide needle placement for photodynamic therapy in the prostate. Necrosis is produced by the interaction of light of a particular wavelength with a photosensitizing agent. The exact mechanism is unknown but a popular theory is that short-lived oxygen radicals are produced and these cause cell death. Necrosis does not occur immediately and the oxygen radicals are MR occult; therefore, MR does not have a monitoring role during the treatment. However, MR is excellent in guiding needle placement (Figures 3 and 4). As many as eight, 19 G hollow needles are introduced trans-

Figure 3 Coronal two-dimensional gradient echo image during photodynamic therapy to the prostate. Two 19 G MR-compatible needles are inserted within the gland and MR is used to confirm the position of the needles

perineally into the peripheral zone of the prostate gland. Multiplanar T_1 -weighted gradient echo images are obtained to confirm needle position and spacing. Laser fibers are introduced through the needles and the tissue is illuminated with red light. Approximately a 16 mm sphere of necrosis is produced around each laser fiber. Treatment is targeted to areas containing tumor on mapping biopsy and away from the urethra, neurovascular bundles, and external sphincter. Imaging assessment of the extent of necrosis is performed using gadolinium-enhanced T_1 -weighted sequences at high field (1.5 T).

Figure 4 Transverse two-dimensional gradient echo image through the prostate during multifiber photodynamic therapy to the gland. Multiple needles are positioned within the tumor in posterior and left-sided lobes of the gland

Necrosis is appreciated as an area of nonenhancement at the treatment site (Figure 5). In comparison, CT demonstrates limited tissue contrast and both gray scale and Doppler ultrasound do not show any specific features.

6.6.2 Brachytherapy

MR guidance of seed insertion has been reported in nine patients at 0.5 T.²⁴ MR allowed confirmation of seed position in three planes. Both T_1 -weighted fast gradient echo and proton density fast spin echo sequences have been used satisfactorily.^{25,26}

6.6.3 Cryotherapy

During cryotherapy, the iceball can be well visualized, although actual temperature measurement is not available. MR has also been used in the follow-up of cryotherapy-induced changes. Contrast-enhanced T_1 -weighted images show necrosis as areas of nonenhancement. Expected changes on follow-up include a reduction in prostatic volume of 30–52%, loss of zonal architecture in 81–100%, and soft tissue thickening of the rectal wall (47%) or around the capsule and neurovascular bundles in the majority (89%).^{27–29}

6.6.4 Laser-induced Thermotherapy in Benign Prostatic Hypertrophy

MR has been used for monitoring of thermal ablation in benign prostatic hypertrophy and for follow-up assessment. On-line monitoring is feasible using phase-frequency shift³⁰ providing an accurate prediction of final lesion size in ten of 13 patients in one study.³¹ Follow-up MR showed lack of gadolinium enhancement in necrotic areas and volume reduction.³²

Figure 5 Transverse contrast-enhanced T_1 -weighted image through the prostate 5 days after photodynamic therapy (PDT). A lobulated region of nonenhancement is seen within the gland that corresponds to the region of devascularization after PDT. Similar changes are seen after cryotherapy

6.6.5 Conclusion

MR guidance and follow-up is preferable to other techniques in prostate ablation; for cryotherapy and thermal techniques there is the added advantage of treatment monitoring.

7 NAVIGATIONAL DEVICE

As indicated above, accurate placement of tools is essential for thermal therapies to ensure that lesions are accurately localized and damage to collateral tissue is avoided. Although freehand placement is usually adequate where lesions are superficial and large, the same is not true for deep and small lesions. In these cases, tool placement may be facilitated by navigational devices. There are a number of systems being

Figure 6 Navigational pointing device. A number of highly reflective balls are mounted on the handle of the pointing device, the light being detected by the stereoscopic camera. Tools may be mounted onto the device to facilitate accurate placement within the target

developed currently. We are investigating the use of a passive navigation device for interactive definition of the slice selection plane. The device can potentially increase the speed with which needles are positioned as it is possible to define the image slice automatically, during needle insertion, according to the orientation of the needle itself. The biopsy needle within its holder is attached to the passive navigation probe (Figure 6). The reference point for image slice selection can be set relative to the tip of the needle. The stereoscopic camera detects the position and rotation of the probe so as to define the slice selection axis. In situations where multiple needles require accurate positioning, the device reduces any ambiguity in identifying needles and so increases the safety of the procedure.

8 SUMMARY

Temperature-sensitive MRI can be achieved for the monitoring of thermal treatments in the body within a realistic scan time. Low-field open-access scanners offer good surgical access to the patient. However, the image quality is poor compared with that expected from high-field closed-bore magnet systems. Several of the temperature-dependent mechanisms of contrast are field strength dependent; consequently, for these, high-field magnets should be preferable for the monitoring of thermal interventions in the body. The development of shorter and wider bore high-field magnets should also assist in the promotion and acceptance of MRI monitoring of thermal interventions in the body, head, and extremities.

1 INTRODUCTION

In solids containing both magnetic nuclei and unpaired electrons, polarization transfer can be obtained between the electron and nuclear spin systems by irradiating at or near the electron Larmor frequency. The result is an enhanced nuclear polarization and, henceforth, an enhanced NMR signal. This effect is called dynamic nuclear polarization (DNP).

Several mechanisms can be responsible for the DNP phenomenon. In 1953, Overhauser predicted that in metals the NMR signal could be enlarged by saturating the resonance line of the conducting electrons: the Overhauser effect.¹ Carver and Slichter² showed experimentally in metallic lithium that Overhauser's revolutionary concept was correct.

Later on, Abragam and Proctor³ and, independently, Jeffries⁴ and Erb et al.⁵ found the occurrence of a DNP effect in solids containing fixed, mutually more or less isolated, unpaired electrons: the solid state effect. Finally, a third DNP effect has also been observed: the thermal mixing effect, which is present when the concentration of (fixed) unpaired electrons is so high that the mutual dipolar interactions between the electrons become comparable to the other interactions between the electrons and their surroundings. Provotorov⁶ showed that in that case the electron spin system can be characterized by two polarizations: one associated with the population distribution over the Zeeman levels and one associated with the population distribution over the internal local magnetic fields which the electrons are experiencing. These polarizations may change if off-resonance irradiation is applied. Abragam and Borghini⁷ used the results of Provotorov and showed that when the polarization associated with the local fields is changed, the nuclear polarization changes as well, due to a coupling between these two polarizations induced by the irradiating microwave field: the indirect thermal mixing effect. Goldman⁸ remarked that this coupling could be present also in the absence of microwave irradiation, and its significance for DNP was shown by Buishvili:⁹ the direct thermal mixing effect. The thermal mixing effects become especially important

when the nuclear Larmor frequency is comparable to or smaller than the ESR line width.

In principle large NMR signal enhancements can be obtained via DNP, maximal of the order of the ratio of the gyromagnetic ratios of the electrons and the nuclei. For example, for protons this would result in an enhancement factor of 660, and for ¹³C nuclei this factor would be as large as 2600. In the earlier days of DNP this aspect was mainly used and applied for the production of polarized targets used in high-energy physics or to study magnetic ordering in the μ K region. However, during the past 15 years new applications have emerged as well. This has been achieved by combining DNP with modern solid state NMR techniques such as cross polarization (CP), magic angle spinning (MAS), and two-dimensional NMR spectroscopy. As a result, more detailed information about structures and dynamics of materials amenable to DNP NMR could be obtained than would have been possible without DNP.

DNP NMR spectroscopy can be applied successfully in a large variety of solid materials such as those in which the unpaired electrons occur naturally, e.g., in the form of dangling bonds, materials in which bond ruptures have occurred, e.g., resulting from pyrolysis or ionizing radiation, materials containing paramagnetic impurities, and materials doped with a suitable paramagnetic agent. In this paper several applications of DNP NMR spectroscopy in solid materials research will be given following a brief description of the DNP phenomenon. Finally, some future aspects of the technique will be discussed.

2 THEORY

Extensive reviews of the different DNP effects have been given elsewhere.^{10–14} Here we shall confine ourselves to a short treatment of the main features of DNP. We shall restrict ourselves to discussing only the Overhauser and the solid state effects. Hence we shall neglect the thermal mixing effects. The main reasons for this omission are that in many cases the Overhauser and solid state effects dominate, and that the overall features of the thermal mixing effects are not much different from that of the solid state effect. Moreover, the thermal mixing effects require a rather lengthy derivation, which is beyond the scope of this article.

As is necessary in the description of any NMR experiment, we have to start with the Hamiltonian. For an electron–nuclear spin system the relevant Hamiltonian is given by

$$\hat{\mathcal{H}} = -\omega_e \hat{S}_z - \omega_n \hat{I}_z + \hat{\mathcal{H}}_{ee} + \hat{\mathcal{H}}_{en} + \hat{\mathcal{H}}_{nn} \quad (1)$$

The first two terms are the Zeeman interactions of the electrons and nuclei, respectively, where $\hat{S}_z = \sum_{j=1}^{N_e} \hat{S}_z^j$ are the electron spin operators and $\hat{I}_z = \sum_{i=1}^{N_n} \hat{I}_z^i$ are the nuclear spin operators. The term N_e is the number of unpaired electrons and N_n is the number of nuclei. Furthermore, in equation (1), $\omega_e = \gamma_e B_0$ and $\omega_n = \gamma_n B_0$, where γ_e and γ_n are the magnetogyric ratios of the electrons and nuclei, respectively, and B_0 is the external magnetic field strength. Finally, $\hat{\mathcal{H}}_{ee}$, $\hat{\mathcal{H}}_{en}$, and $\hat{\mathcal{H}}_{nn}$ denote the spin–spin interactions between the electrons, between the electrons and the nuclei, and between the nuclei, respectively. For DNP, the most

important term in equation (1) is the so-called hyperfine interaction term $\hat{\mathcal{H}}_{\text{en}}$. In general, this term consists of two parts, the scalar interaction term $\hat{\mathcal{H}}_{\text{en}}^s$ and the dipolar term $\hat{\mathcal{H}}_{\text{en}}^d$. The scalar interaction arises from a finite electron spin density at the nuclear sites, either directly from the unpaired electron itself or mediated by bonding electrons polarized by the unpaired electrons.

Before describing the DNP phenomenon we first consider the energy level scheme of electron–nuclear spin pairs. For simplicity we restrict ourselves to nuclear spin- $\frac{1}{2}$ systems, with positive γ_n values. The result is then the simple four-energy-level scheme given in Figure 1. Also given are the nuclear and electron quantum numbers, m_n and m_e , respectively (for the electrons the highest energy state corresponds to $m_e = +\frac{1}{2}$, because γ_e is negative), and as usual we denote a state in which, for example, $m_n = +\frac{1}{2}$ and $m_e = -\frac{1}{2}$ by the notation $|+-\rangle$. Finally, the amount of nuclei in each state is denoted by N_{n1}, N_{n2} , etc. Then, defining $N_n^+ = N_{n2} + N_{n4}$ and $N_n^- = N_{n1} + N_{n3}$ as the total amounts of nuclei in the + and – states, respectively, we can define the nuclear polarization, P_n , as

$$P_n = \frac{N_n^+ - N_n^-}{N_n^+ + N_n^-} = \frac{N_n^+ - N_n^-}{N_n} = \frac{\Delta N_{12} + \Delta N_{34}}{N_n} \quad (2)$$

In Figure 1 the situation of thermal equilibrium is depicted, where the population distribution is governed by the Boltzmann distribution corresponding to the lattice temperature. Then P_n is defined as P_n^0 . Similar expressions can be given for the electron polarization, P_e , and its thermal equilibrium value, P_e^0 . It can easily be derived that in the high-temperature approximation, where $\hbar\omega_e/kT_L, \hbar\omega_n/kT_L \ll 1$, P_n^0 and P_e^0 are given by

$$P_n^0 = \frac{1}{2} \omega_n \hbar (kT_L)^{-1} \quad \text{and} \quad P_e^0 = \frac{1}{2} \omega_e \hbar (kT_L)^{-1} \quad (3)$$

Figure 1 The Zeeman energy level scheme of electron–nuclear spin pairs. The population distribution over the energy levels depicts the thermal equilibrium situation

where T_L is the lattice temperature. It follows from equation (3) that the thermal equilibrium polarization of the electrons is a factor γ_e/γ_n larger than that of the nuclei. It is this difference in polarization that is used in DNP, which we shall now consider.

2.1 The Overhauser Effect

The Overhauser effect occurs when $\hat{\mathcal{H}}_{\text{en}}$ is time-dependent on a timescale of the order ω_e^{-1} . Then $\hat{\mathcal{H}}_{\text{en}}(t)$ causes relaxation transitions between the various levels depicted in Figure 1, which, when combined with an irradiation at the electron Larmor frequency, results in a change in the nuclear polarization.

In order to illustrate this, we assume that the scalar interaction term, $\hat{\mathcal{H}}_{\text{en}}^s$, dominates. It can be shown that $\hat{\mathcal{H}}_{\text{en}}^s$ causes a relaxation transition between the $|+-\rangle$ and $|-\rangle$ states of the electron–nuclear system, hence between the levels 1 and 4 in Figure 1. We shall call this relaxation rate W_{14}^s , which is given by $W_{14}^s = \frac{1}{2} \overline{a_{ij}^2} J(\omega_e + \omega_n, \tau_c)$; $J(\omega, \tau_c)$ is the spectral density function characterizing the time dependence, $\overline{a_{ij}^2}$ is the time-averaged value of a_{ij}^2 , where a_{ij} denotes the strength of the scalar interaction. As with all relaxation transitions, after some population distortion W_{14}^s restores the Boltzmann distribution between the energy levels connected by W_{14}^s , hence between levels 1 and 4. Now suppose that we are irradiating with a microwave field of amplitude B_1 and a frequency ω close to ω_e . This means that we are irradiating between the electron Zeeman levels 1 and 3 respectively 2 and 4 with an induced transition probability $W/2 = (\pi/2) \gamma_e^2 B_1^2 g(\omega - \omega_e)$, where $g(\omega)$ is the normalized lineshape function of the ESR line.

Suppose also that W is large enough to saturate the ESR line completely. Then in the stationary situation, the population distribution over the various levels becomes as given in Figure 2. Due to the saturating irradiation the population of level 1 becomes equal to that of level 3, and the population of level 2 becomes equal to that of level 4. Due to the relaxation transition, W_{14}^s , the Boltzmann distribution exists between the levels 1 and 4. As a result, the population differences between the nuclear Zeeman levels 1 and 2 respectively 3 and 4 is increased: the nuclear polarization is (positively) enhanced. The enhancement curve, which is the Overhauser enhancement factor as a function of the irradiation frequency ω , reflects the (saturated) ESR line, and is symmetrical about ω_e for symmetrical ESR lines. The enhancement becomes maximal for $\omega = \omega_e$. An Overhauser effect also occurs when the (time-dependent) dipolar electron–nuclear interactions, $\hat{\mathcal{H}}_{\text{en}}^d$, dominate. It can be shown that $\hat{\mathcal{H}}_{\text{en}}^d$ causes relaxation transitions between all four energy levels, so that the result becomes more complicated. However, it can be shown that often the relaxation transition between the levels 2 and 3 dominates, and the reader can easily convince himself that in this situation the nuclear polarization enhancement becomes negative.

The question arises under which circumstances we can expect to observe an Overhauser effect. As already stated above, a time-dependence in $\hat{\mathcal{H}}_{\text{en}}$ is needed with a correlation time of the order of $(\omega_e \pm \omega_n)^{-1} \simeq \omega_e^{-1}$, which in practice means that τ_c has to be of the order 10^{-11} to 10^{-12} s. In

Figure 2 The Overhauser effect due to the scalar electron–nuclear interactions. The population distribution over the energy levels depicts the stationary situation

solids, the molecular motions are almost never that fast, so that an Overhauser effect due to this type of motion is highly unlikely. However, other processes may occur in solids that do provide the required time dependence: (1) in conductors or semiconductors, the conducting electrons move very rapidly through the lattice, rendering the spatial coordinates in $\hat{\mathcal{H}}_{\text{en}}$ time-dependent on a fast scale (this explains the success of observing an Overhauser effect in metals²); (2) in solids with large amounts of unpaired electrons and/or with electrons with a delocalized electron density distribution, strong electron–electron spin exchange interaction may occur.¹⁵ These interactions, which arise from electrostatic Coulomb interactions, cause a time-dependence in the electron spin operator $\hat{S}$ occurring in $\hat{\mathcal{H}}_{\text{en}}$, and hence in $\hat{\mathcal{H}}_{\text{en}}$ itself. Also this time-dependence can be fast enough to fulfill the requirements for the Overhauser effect.¹⁰ An example is the Overhauser effect observed in graphite and other solids containing large aromatic clusters.

2.2 The Solid State Effect

The solid state effect occurs in solids with fixed paramagnetic centers and with electron–nuclear interactions that are time-independent or only slowly time-dependent, with correlation times typically larger than about 10^{-5} s. The presence of $\hat{\mathcal{H}}_{\text{en}}$ means that there exist, beside the external B_0 field, static local magnetic fields in the sample, partly oriented perpendicular to B_0 . It is well known from second-order perturbation theory that the result of such interactions is that the electron–nuclear states can no longer be described by the pure product functions given in Figure 1, but become mixed with other states. The admixture coefficient depends on the energy

Figure 3 The solid state effect due to the forbidden transition W^- . The population distribution over the energy levels depicts the stationary situation

difference between the levels corresponding to the states and increases with decreasing energy differences. Hence, in highest order, the mixture occurs between the states corresponding to the levels 1 and 2 respectively 3 and 4. The result is given in Figure 3, where q (and its complex conjugate q^*) denotes the admixture coefficient. It should be emphasized that q is small, typically of the order 10^{-3} to 10^{-4} . Nevertheless, these small admixtures have as an important consequence that irradiation with a frequency $\omega_e - \omega_n$ or $\omega_e + \omega_n$ leads to a nonzero transition probability between the levels 2 and 3 respectively 1 and 4.

In order to understand this we consider the effect of irradiating with a frequency $\omega_e - \omega_n$. If the eigenstates were not mixed nothing would happen, because the matrix element $\langle -- | \hat{\mathcal{H}}_{\text{rf}} | ++ \rangle$ is zero as the Hamiltonian $\hat{\mathcal{H}}_{\text{rf}}$ representing the rf irradiation is proportional to single spin operators. However, if the eigenstates are mixed, a small but nonzero transition probability is obtained because now nonzero matrix elements such as $-q \langle + - | \hat{\mathcal{H}}_{\text{rf}} | ++ \rangle$ occur. This is called the ‘forbidden’ transition, W^- . Similar results are obtained for irradiation at $\omega_e + \omega_n$, giving rise to a ‘forbidden’ transition W^+ . The quantities W^+ and W^- are given by

$$W^\pm = 2|q|^2 \pi \gamma_e^2 B_1^2 g(\omega_e - \omega \pm \omega_n) \quad (4)$$

The effect of irradiating at $\omega_e - \omega_n$ on the nuclear polarization is depicted in Figure 3. Here we have also incorporated the effect of the electron Zeeman relaxation rate, W_{ze} . Then, in the stationary situation, W_{ze} maintains the Boltzmann distribution between the electron Zeeman levels 1 and 3 with respect to 2 and 4, whereas W^- equalizes the populations of levels 2 and 3. The result is a positive enhancement of the nuclear polarization P_n : the solid state effect. In a similar way it can be shown that irradiation at $\omega_e + \omega_n$ leads to a negative enhancement of P_n . For symmetrical ESR lines the solid state enhancement curve, which is the enhancement factor as a function of the irradiation frequency ω , is antisymmetrical about ω_e . The enhancement becomes maximal for $\omega = \omega_e \pm \omega_n$.

In Figure 4 examples are given of enhancement curves due to the various DNP effects, including the effects of thermal mixing. As mentioned before we will not treat thermal mixing in any detail. Here we confine ourselves to remarking that,

Figure 4 The enhancement curves of the various DNP effects: curve 1, solid state effect; curve 2, indirect thermal mixing effect; curve 3, direct thermal mixing effect; curve 4, Overhauser effect. Reproduced by permission of Marcel Dekker, Inc., from R. A. Wind, in 'Modern NMR Techniques and Their Application in Chemistry', eds. A. I. Popov and K. Hallenga, 1991, p. 125

like the enhancement curve due to the solid state effect, the thermal mixing enhancement curves are antisymmetrical about ω_e for symmetrical ESR lines. The direct effect of thermal mixing becomes maximal when the offset frequency, $\omega - \omega_e$, is comparable to the ESR linewidth, whereas indirect thermal mixing gives a maximal enhancement for offset frequencies between those for which the direct thermal effect and the solid state effect become maximal.

2.3 Enhancement Factors

As already mentioned in the Introduction, in theory large DNP enhancement factors can be expected, of the order of γ_e/γ_n . However, in practice, several factors can limit the magnitude of the enhancement factor which is actually obtained. We shall illustrate this for enhancements by the Overhauser and solid state DNP effects (for a more general treatment the reader is referred elsewhere^{13,14,16,17}). For the Overhauser effect, we have already remarked that DNP enhancement can be positive or negative, depending on whether the scalar or the dipolar electron–nuclear interactions dominate. As a consequence, as in general both types of interactions are present, the enhancement is reduced and can become almost zero in unfavorable cases.

In the solid state effect, irradiation with a frequency ω can lead simultaneously to both forbidden transition probabilities W^- and W^+ . This is especially the case when the ESR linewidth is comparable to the ω_n , see Figure 5 (in fact, as is shown in the figure, irradiation can result in both the allowed transition probability, W , and the forbidden transition probabilities W^- and W^+). As W^- and W^+ result in enhancements of opposite sign, the result is a decreased solid state enhancement, the so-called unresolved solid state effect. This can occur especially for low γ_n nuclei, for which ω_n is small. (However, it can be shown^{13,14} that in these cases the enhancements due to thermal mixing increase, so that

Figure 5 The allowed and forbidden transition probabilities as a function of the offset frequency $\Delta = \omega - \omega_e$. Irradiation at Δ_0 simultaneously leads to W , W^- , and W^+

the overall enhancement can still be large.) Other parameters that determine the enhancements are the amount of unpaired electrons, N_e , which has to be relatively large; the ESR linewidth, which should be small; the electron spin–lattice relaxation rate, W_{ze} , which should be large; the amplitude of the microwave field, B_1 , which should be large; the external magnetic field, B_0 , which should be small in order to obtain appreciable forbidden transition rates (this is only important for the solid state effect); the nuclear Zeeman relaxation rate, which should be small; and the correlation time τ_c characterizing the time dependence in $\hat{\mathcal{H}}_{en}$. As has already been mentioned, if $\tau_c \approx \omega_e \approx 10^{-11}$ to 10^{-12} s, the Overhauser effect dominates, whereas the solid state effect is observed when $\tau_c \geq 10^{-5}$ s. For τ_c values between these limits, both effects are small; if electron–nuclear interactions exist with different time constants, both effects might be present. We shall encounter this situation later.

The author and others^{14,16,17} have given expressions for the different enhancement factors, from which the enhancements can be calculated if the various parameters mentioned above are known. For instance, for abundant-spin systems with large γ_n values and fixed paramagnetic centers, appreciable solid state enhancement factors (a factor 10 or more) can be expected under the following conditions: $N_e \geq 10^{24} \text{ m}^{-3}$; ESR linewidth $\leq 1 \text{ mT}$; W_{ze}^{-1} of the order of $\mu \text{ s}$; $B_1 \geq 0.03 \text{ mT}$; $B_0 = 1.4 \text{ T}$; nuclear Zeeman relaxation time $\geq 1 \text{ s}$. For rare-spin systems with small γ_n values, the enhancement factors are often at least an order of magnitude larger, which is mainly due to larger Zeeman relaxation times and an increased importance of the direct thermal mixing effect.¹⁴

It should be kept in mind, however, that these parameters are not independent of each other, and that large enhancements have been observed under completely different conditions. For instance, in natural diamonds a large ^{13}C enhancement factor of 200 is observed¹⁴ despite the small value of N_e ($\approx 10^{22} \text{ m}^{-3}$). The reason is the large carbon Zeeman relaxation time ($\approx 2000 \text{ s}$) occurring in this material.

3 APPLICATIONS OF DNP NMR

Both the DNP enhancement curves and the DNP-enhanced NMR spectra can be used to obtain detailed and often unique information about the chemical and physical properties of solid materials, and representative illustrations of such applications will be given in this section. All experiments that will be

described have been performed in an external field of 1.4 T, corresponding to an electron Larmor frequency of 40 GHz and nuclear Larmor frequencies of 60 MHz for protons, 15 MHz for ^{13}C nuclei, and 12 MHz for ^{29}Si nuclei. Elaborate descriptions of the experimental setups, including the probes have been given.^{18,19} All measurements were performed at room temperature.

3.1 The DNP Enhancement Curves

The symmetrical or antisymmetrical character of the DNP curve makes it possible to determine whether the electron–nuclear interactions are time-dependent, time-independent, or whether both types of interactions are present. This is illustrated in Figure 6, where are given the enhancement curves for ^1H and ^{13}C using DNP for a low-volatile bituminous coal. The ^1H DNP curve, Figure 6(a), contains both a symmetric and antisymmetric contribution, presumably because part of the electrons undergo rapid spin-exchange interactions whereas other electrons behave as fixed paramagnetic centers. The ^{13}C curve, Figure 6(b), is antisymmetric within experimental error, probably due to the much larger enhancements resulting from the static electron–carbon interactions, which overshadow the relatively small Overhauser enhancement. The occurrence of both the Overhauser and solid state effect in the ^1H DNP curves has been observed in a large variety of coals of different rank,²⁰ as well as in cellulose heat-treated in the temperature range 250–1000 °C.²¹ It was found that for heating temperatures above 275 °C unpaired electrons were formed as a result of band ruptures and a DNP effect was observed. In the lower temperature range, up to ca. 450 °C, the solid state and thermal mixing effects dominate, whereas, between 450 °C and 700 °C, it is mainly an Overhauser effect which is observed (above 700 °C no DNP effect may be measured because the ESR line becomes very broad). However, the DNP enhancement curves indicate that an Overhauser effect also

exists in the low temperature range, and that the solid state and thermal mixing effects are present for heating temperatures up to 500 °C. This is attributed to the small amounts of unpaired electrons undergoing rapid spin-exchange interactions at low temperatures, and behaving as fixed centers at the higher temperatures, respectively. In fact, it could be shown that the DNP curves could be used to detect fractions of electrons smaller than 1% either behaving as fixed centers or submitted to exchange interactions.

3.2 DNP and High-Resolution NMR in Solids

The increase in the NMR signal due to DNP can be used to reduce measuring times or to measure relatively small amounts of compounds. This ability is especially important for NMR spectroscopy on rare-spin species where, in the absence of DNP, long measuring times, several hours or more, are required in order to obtain an acceptable signal-to-noise ratio. In this section we shall give examples of such DNP NMR experiments.

In solids containing, besides unpaired electrons, both abundant spins and rare spins, the rare-spin polarization can be enhanced via DNP in two ways. (1) *Indirectly*, by first enhancing the abundant-spin polarization followed by a polarization exchange between the abundant and rare spins via cross polarization (CP). This is called the DNP CP (or DNP CP MAS when magic angle spinning is applied as well) experiment. In those cases where both the abundant spins and the electrons are homogeneously distributed in the sample, the spin diffusion among the abundant nuclei is generally strong enough to establish a single, average, polarization enhancement for all abundant nuclei, resulting, after CP, in an enhanced, undistorted, NMR spectrum of the rare nuclear spins. (In compounds where the electrons and/or the abundant nuclei are not homogeneously distributed, a distribution in DNP enhancements may also occur. As we shall see later, this effect can be used selectively to study interfaces and surfaces.) (2) The rare-spin polarization can also be enhanced *directly* via a polarization exchange between the electrons and the rare nuclei. This experiment, in which the rare-spin NMR signal is observed via a standard 90° rf pulse, will be called the DNP SP (MAS) experiment (SP = single pulse). Of course, in materials such as ceramics and diamonds, which do not contain abundant spins, DNP SP is the only possible technique. As the spin diffusion between rare spins is small, a distribution of enhancement factors often exists in the DNP SP experiment with larger enhancements for the nuclei in the vicinity of the unpaired electrons.¹⁴ This has the disadvantage that distortions can occur in the DNP SP NMR spectra, but has the (potentially powerful) advantage that this experiment makes it possible selectively to probe structures and dynamics near the unpaired electrons.

It should be noted that in solids containing both rare and abundant nuclear spins, even in a DNP SP experiment the rare spin polarization can also be enhanced indirectly via a polarization exchange with the abundant spins. This has been called the three-spin effect.²² This phenomenon is observed in cases that the rare-spin Zeeman relaxation is dominated by the interactions between the rare and abundant nuclear spins. Hence this effect is more likely to occur for rare nuclei remote from the unpaired electrons, where the electron–nuclear

(a): Result of an SP experiment; (b) and (c): Results of a DNP SP experiment without (b) and with (c) proton saturation. Reproduced by permission of the Academic Press from G. G. Maresch, R. D. Kendrick, C. S. Yannoni, and M. E. Galvin, *J. Magn. Reson.*, 1989, **82**, 41

interactions become weak. The three-spin effect arises from the nuclear Overhauser effect (NOE). This is similar to the Overhauser effect described in Section 2. The only differences are that NOE is caused by nuclear–nuclear interactions instead of electron–nuclear interactions, and that NOE is due to dipolar interactions only. It follows from Section 2 that NOE leads to a positive polarization enhancement of the rare-spin polarization if the abundant spin polarization is decreased via saturation (assuming that the gyromagnetic ratio of the nuclei is positive). However, if the abundant spin polarization is, for example, positively enlarged via DNP, the NOE enhancement of the rare spins becomes negative. Consequently, in a rare-spin DNP SP experiment, a positive direct enhancement from the electrons can be counteracted by a negative NOE enhancement. The three-spin effect is illustrated in Figure 7 where ^{13}C spectra are shown of a polymer consisting of small islands of *trans*-polyacetylene (PA) embedded in a matrix of polyethylene (PE). In *trans*-polyacetylene, $(\text{CH})_x$, unpaired electrons (the so-called solitons) are present, presumably arising from bond-alternation domain walls.²³ These solitons move rapidly over the chains at least part of the time, giving rise to an Overhauser effect.^{14,24} It follows that for the ^{13}C line around 20 ppm, which is due to the PE carbons which are

Figure 8 ^{13}C spectrum of *trans*-polyacetylene, obtained via ^1H – ^{13}C DNP CP MAS NMR. The main line at 135 ppm is due to the ^{13}C nuclei inside the $(\text{CH})_x$ chains; structural defects responsible for the other lines are indicated in the figure

for the major part remote from the solitons in the PA chains, the NOE effect leads to a negative enhancement in a DNP SP experiment without proton saturation. However, the ^{13}C line around 200 ppm is due to the carbons in the PA chains. Here the soliton–carbon interactions are so strong that the NOE effect is not observed. The three-spin effect can be avoided by partially saturating the abundant-spin polarization to such an extent that the polarization remains at its thermal equilibrium value.

We shall now consider applications of the DNP CP MAS and DNP SP MAS experiments.

3.2.1 Increase in Sensitivity

The increase in sensitivity due to DNP can result in dramatic decreases in the measuring time of an experiment. This can be used, for instance, for a fast (of the order of minutes) characterization of coal,²⁰ ceramics,²⁵ and diamonds,¹⁴ to perform two-dimensional experiments in a relatively short time²⁴ (in this latter case, a two-dimensional experiment is reported for PA which would have required a measuring time of 165 years without DNP!), or to detect small amounts of molecules. An example of the latter application is shown in Figure 8 where the (natural abundance) ^{13}C DNP CP MAS spectrum of *trans*-polyacetylene is shown. Despite the fact that the amount of material was small (8 mg), the ^1H enhancement was so large (27-times in this experiment), that a ^{13}C spectrum with an excellent signal-to-noise ratio was obtained in a relatively short time.²⁶ In fact, it can be determined that the small narrow line at 13 ppm, which is due to the methyl end groups of the polyacetylene chains, represents only 0.5% of the total amount of carbons, or 3×10^{16} ^{13}C nuclei.

3.2.2 Structures and Dynamics Near the Unpaired Electrons

An example of the type of local information that can be obtained via DNP is shown in Figure 9. In this figure, ^{13}C spectra are shown of *trans*-polyacetylene obtained after a few

Figure 9 ^{13}C spectra of *trans*-polyacetylene, exposed to air for 4 months, obtained via (a) DNP CP MAS NMR and (b) DNP SP MAS NMR

months of exposure of the sample to air. Figure 9(a) shows the result of a DNP CP MAS experiment on ^{13}C . Compared with Figure 8, it follows that extra lines are observed due to the formation of ethene oxide groups, oxygen bridges, hydroxyl groups, and carbonyl groups.²⁷ Figure 9(b) shows the spectrum obtained via a ^{13}C DNP SP MAS experiment. We observe here that only the carbons in the $(\text{CH})_x$ chains are detected. Hence in the latter experiment mainly the carbons in the chains below the surface are observed. These are not affected by exposure to the air.

Another type of local information that can be obtained via DNP SP MAS is the spin-density distribution of the unpaired electrons over the molecules.²⁶ An example of this possibility is the organic conductor $(\text{fluorantheny})_2\text{PF}_6$. At room temperature this material behaves as a one-dimensional metal where the conduction electrons move more or less freely along paths parallel to the molecular stacks.²⁸ The electron mobility is so large that only an Overhauser effect is observed in this sample.²⁹ The average enhancement for ^1H is positive. This means that the dominating electron–proton hyperfine interaction is scalar. As a consequence, the overall enhancement of the DNP CP MAS spectrum of ^{13}C is positive as well, and Figure 10(a) shows the result of such an experiment. However, completely different results are obtained in the DNP SP MAS experiment on ^{13}C , shown in Figure 10(b). Here some lines are enhanced positively, indicative of a dominant electron–carbon scalar interaction, and one line is enhanced negatively due to a dominating electron–carbon

Figure 10 ^{13}C spectra of $(\text{fluorantheny})_2\text{PF}_6$, obtained via (a) DNP CP MAS NMR and (b) DNP SP MAS NMR. Reproduced by permission of Marcel Dekker, Inc., from R. A. Wind, in 'Modern NMR Techniques and Their Application in Chemistry', eds. A. I. Popov and K. Hallenga, 1991, p. 125

dipolar interaction, whereas for the other lines the two DNP effects eliminate one another, resulting in a negligibly small enhancement. This phenomenon is due to the distribution of the electron density over the fluorantheny molecules, which is different at the different sites of the carbons, resulting in different ratios of the electron–carbon scalar and dipolar interactions. Hence, experiments utilizing DNP SP MAS can be used to determine the electron density distribution over the sites of the chemically different carbons.

Another application of DNP NMR in conductors is the determination of Knight shifts.²⁹ The Knight shift is proportional to the polarization of the conducting electrons. Hence, by saturating the ESR line, not only a signal enhancement due to DNP is obtained, but the Knight shift is suppressed as well. It has been shown²⁹ that for $(\text{fluorantheny})_2\text{PF}_6$ the Knight shifts in the various carbon lines could be separated from the 'ordinary' chemical shift.

3.2.3 Interfaces and Surfaces

An example of an interfacial study with DNP NMR is an investigation of an immiscible mixture of polycarbonate

Figure 11 ^{13}C CP MAS NMR spectra of polycarbonate/polystyrene blends (a) with and (b) without ^1H DNP. The difference spectrum (c) has two features: the intensity around 40 ppm is due to the sp^3 -hybridized carbons in PS whereas the intensity around 120 ppm arises from the carbons in the PC chains at the interface. Reproduced by permission of the American Society from M. Afeworki, R. A. McKay, and J. Schaefer, *Macromolecules*, 1992, **25**, 4084

(PC) and polystyrene (PS).^{19,30} The samples consisted of thin film blends in which the polystyrene was doped with the stable radical BDPA [1,3-bis(diphenylene)-2-phenylallyl]. The interfacial region of PC could then be studied by measuring the DNP enhancement of protons via ^1H - ^{13}C DNP CP MAS NMR. Figure 11 shows the results of such a measurement, carried out on a blend consisting of PC, which is labeled at the 3 and 3' ring positions with 99 atom% ^{13}C , and PS, which is ^{13}C -depleted in all phenyl ring carbons. In this way, interferences between the NMR resonances of the aromatic carbons of the two polymers, which are partially overlapping, were avoided, and the peak observed at 120 ppm was almost exclusively due to the ^{13}C -labeled sites in PC. As the unpaired electrons in BDPA behave as fixed paramagnetic centers, the DNP enhancement of ^1H is mainly due to the solid state effect. Figure 11(a) and (b) show the ^1H - ^{13}C CP MAS spectra obtained with and without ^1H DNP, respectively. It follows that the protons in PS, which are close to the unpaired electrons, are enhanced to the greatest extent (a factor of 20) and that there is also a small but noticeable enhancement for the protons in PC. This can be seen more clearly in Figure 11(c) where the differential spectrum is given. It has been shown^{30a} that the proton polarization in PC is enhanced due to direct polarization transfer from these protons to the electrons, and that the signal of ^{13}C in PC observed in the differential spectrum arises from a 60 Å region from the PC/PS boundary which is 2% of the PC film thickness. Moreover, the

Figure 12 ^{13}C spectra of a 14% ^{13}C -enriched CVD diamond film, obtained via (a) DNP SP MAS NMR, (b) SP MAS NMR, (c) ^1H - ^{13}C DNP CP MAS NMR, and (d) ^1H - ^{13}C CP MAS NMR. Reproduced by permission of the American Institute of Physics from H. Lock, R. A. Wind, and G. E. Maciel, *J. Chem. Phys.*, 1993, **99**, 3363

authors were able to show that the interfacial aromatic carbons in PC have less motion than that of the bulk-PC aromatic carbons. This was attributed to restricted interchain motions resulting from a more dense packing for the PC chains near the PS barrier.

An example of a surface that can be studied via DNP NMR is provided by an investigation of chemical vapor deposited (CVD) diamond films.³¹ Figure 12 shows ^{13}C spectra of a 14% ^{13}C enriched diamond film prepared by microwave-plasma-assisted CVD, using CH_4 and H_2 as feed gases.^{31b} During the formation of the diamond films, unpaired electrons occur in the form of dangling bonds, which can be used for DNP measurements. Figure 12(a) and (b) show the results of ^{13}C DNP SP MAS NMR and SP MAS NMR, respectively, illustrating the increase in sensitivity due to DNP (the ^{13}C DNP enhancement factor is 50). Figure 12(c) and (d) show ^{13}C spectra obtained via ^1H - ^{13}C DNP CP MAS and CP MAS NMR. A small percentage of protons (<0.1 atom %) is present at the intergrain boundaries of the diamond, and DNP can be used to enhance the proton signal (the enhancement factor is 25). It follows from Figure 12(c) that the hydrogenated diamond surfaces give rise to new resonances in the carbon spectrum (it was shown that the broad resonance at around 45 ppm actually consists of two lines), and the chemical shifts corresponding to these lines have been used to investigate the possibilities of different 'diamondoids', hydrogen-bearing carbon structures, occurring at the surfaces.^{31b}

4 SUMMARY, CONCLUSIONS, AND PERSPECTIVES

High-resolution NMR combined with microwave-induced DNP has resulted in new areas of rare-spin NMR studies in solids. In many materials large DNP enhancement factors have been observed, which made possible NMR experiments which could not have been performed without DNP. The maximum proton enhancement that has been measured in a probe capable of MAS was 60, carbon enhancements of a few hundred were no exception, and in a ceramic fiber a silicon

enhancement factor 1000 was reported.²⁵ Although the DNP enhancements were not so large in some other materials, it should be kept in mind that even smaller enhancements can be very useful as they cause a reduction in the measuring time proportional to the square of the enhancement. Besides increasing the NMR sensitivity, DNP can also be used for other purposes such as the study of the structures and dynamics near the unpaired electrons, the detection of small amounts of electrons undergoing strong exchange interactions or behaving as fixed centers, the determination of the mobility and the spin-density distribution of conducting electrons, the study of surfaces and interfaces, the determination of Knight shifts, and DNP-enhanced imaging.³² Finally, DNP NMR has been applied in a large variety of solid materials, such as doped polymers, coal, pyrolyzed materials, amorphous silica, organic conductors, semiconductors, natural and artificial diamonds, polymer composites, and ceramics.

However, it should be noted that many other possibilities for utilizing DNP NMR still remain to be explored:

1. Other types of radicals such as ions, nitroxide radicals, or radicals resulting from ionizing radiation.
2. Other materials; for example, experiments have already been started to explore the potential of DNP in zeolites, catalysts, and biomaterials.
3. High-resolution DNP NMR on quadrupolar nuclei.
4. High-resolution DNP NMR at different temperatures.
5. High-resolution DNP NMR at different pressures.
6. Combination of DNP with other high-resolution solid NMR techniques such as CRAMPS, fast MAS, DAS, DOR.
7. Combination of high-resolution NMR with different DNP techniques, which have been developed to increase the DNP enhancement factors and to improve the polarization transfer rates. Examples of these new techniques are the NOVEL (Nuclear spin Orientation Via Electron spin Locking) experiment,³³ which is an electron–nuclear analog of the CP experiment, and which provides fast polarization transfer (μ s); the integrated solid effect (ISE),³⁴ where DNP is combined with adiabatic rapid passage through the ESR line, resulting in increased enhancement factors; DNP in the nuclear rotating frame,³⁵ which reduces the polarization transfer time by several orders of magnitude and which can be used to avoid distortion in the CP spectra resulting from rotating frame relaxation effects; DNP in higher external magnetic fields,³⁶ which might improve the resolution of the NMR spectra, and nuclear polarization enhancement using light irradiation. Examples of the latter techniques are microwave-induced optical nuclear polarization (MIONP),³⁷ optically polarized xenon and other rare gases, which can be used to study surfaces³⁸ and optical nuclear polarization (ONP).³⁹ Large enhancements have been obtained; for example, by applying the ISE technique in a naphthalene crystal doped with pentacene, in which the triplet state is highly polarized by photo-excitation, a DNP enhancement factor of the naphthalene protons of 5500 has been found.⁴⁰

It can be expected that this and the other new methodologies and applications will further enhance the applicability of solid state NMR, and that many exciting new results will emerge in the near future.

1 INTRODUCTION

The literature on electron–nuclear hyperfine coupling as measured by NMR is so large that a comprehensive survey would by far exceed the scope of this article. Hence we concentrate on the principles which determine the applicability and the limitations of this method. The selection of the few examples given is necessarily subjective; for reasons discussed below, we have restricted ourselves to free radicals in solution.

The electron–nuclear hyperfine interaction between a nuclear spin and an unpaired electronic spin causes a splitting of the resonance absorption lines of electron paramagnetic resonance (EPR) which is termed ‘hyperfine splitting’ (HFS). The splitting is usually described in terms of a coupling constant a_i for the i th nucleus given either in tesla or in hertz; it was measured in the first 20 years of NMR by analyzing the splitting in the EPR spectrum. While the obtainable resolution of NMR depends mainly on the homogeneity of the external magnetic field B_0 , the resolution of EPR depends on the relaxation phenomena of the unpaired electrons which contribute to the transverse relaxation time T_2 of the electronic spin and hence to the linewidth. It would be outside the scope of this paper to discuss the various mechanisms which contribute to the linewidth—in particular the spin–orbit interaction can broaden the line in metal complexes beyond the resolvability of HFS. It turns out that free radicals in solution are the most suitable systems for studying hyperfine interactions.

The HFS can frequently not be resolved, even in solutions of free radicals consisting of first row elements in low viscosity liquids where the spin–orbit interaction and dipolar broadening are negligible. This is often due to the interaction of the unpaired spins of the electrons with the paramagnetic oxygen O_2 present in most solvents in contact with air. Therefore, the linewidth can be drastically decreased and the resolution correspondingly increased by carefully removing O_2 from the solvent.¹ This is illustrated by the example given in Figure 1, the EPR spectrum of 2,4,6-triphenylphenoxyl in benzene.²

However, even without oxygen the HFS in EPR spectra cannot be resolved in many cases. This is due to the large number of lines in an EPR spectrum because the total number of HFS components equals the product of the number of lines

Figure 1 EPR spectra of 2,4,6-triphenylphenoxyl in benzene (concentration $5 \times 10^{-4} \text{ mol l}^{-1}$): (a) saturated with air, (b) after the exclusion of oxygen

originating from nonequivalent nuclei (nuclei with identical HFS coupling constants are termed ‘equivalent’). If a free radical contains three types of equivalent protons, namely l_i protons with coupling constant a_i , m_j with coupling constant a_j , and n_k with coupling constant a_k , the total number of HFS lines is $(l + 1)(m + 1)(n + 1)$, which easily leads to several hundreds and even thousands of HFS components. If this large number of HFS lines cannot be resolved, the coupling constants can be measured in many cases by means of electron–nuclear double resonance (ENDOR) or electron–nuclear triple resonance.^{3–5} For the example given above, one expects six ENDOR absorption lines, two for each type of equivalent protons. One drawback of ENDOR is that the number of equivalent nuclei that cause an ENDOR transition can usually not be deduced from an ENDOR spectrum, since the intensity of the lines is not proportional to the number of equivalent nuclei, but depends in a complicated manner on the relaxation processes within the sample; we shall not discuss this further here since it is not the topic of this paper, but it is dealt with in another article in this Encyclopedia (see *Electron–Nuclear Multiple Resonance Spectroscopy*).

Although ENDOR may help by very drastically reducing the number of absorption lines in cases where the coupling constants cannot be measured by high-resolution ESR because the number of HFS components is too high, both methods fail in the case of small coupling constants.

2 PRINCIPLE

The interaction of a nucleus with spin $I = \frac{1}{2}$ and a magnetogyric ratio γ_I and an unpaired electron with spin $S = \frac{1}{2}$ and a magnetogyric ratio γ_S in an external magnetic field B_0 can be described by the Hamiltonian

$$\hat{\mathcal{H}} = \gamma_S \hbar (\hat{S} \cdot B_0) + \gamma_I \hbar (\hat{I} \cdot B_0) + \gamma_S \gamma_I \hbar^2 \times \left[\frac{8}{3} \pi |\Psi_{(0)}|^2 (\hat{I} \cdot \hat{S}) + \frac{3(\hat{I} \cdot r)(\hat{S} \cdot r)}{r^5} - \frac{(\hat{I} \cdot \hat{S})}{r^3} \right] \quad (1)$$

The first two terms are the electronic and nuclear Zeeman term; the third term is the scalar Fermi contact term which causes the hyperfine splitting.

Figure 2 Energy levels and transitions in a coupled two-spin system of one electronic spin $S = \frac{1}{2}$ and one nuclear spin $I = \frac{1}{2}$

The fourth term, (the dipolar term) depends explicitly on the angle Θ between the vector $\mathbf{r}$ connecting $\mathbf{S}$ and $\mathbf{I}$ and the magnetic field $\mathbf{B}_0$. The term is averaged out to zero by the molecular motion in low viscosity liquids and hence does not contribute to the time-independent interaction, i.e. the energy levels, but it must be taken into account for the time-dependent interactions, such as relaxation and dynamic nuclear polarization (DNP).

It is instructive to consider the energy levels and possible transitions given by the first three time-independent terms of this two-spin system (Figure 2) the method is easily extended to more nuclei as are present in most practical cases, but the simple example shown in Figure 2 is suitable for understanding the principle. On the left, we recognize the four energy levels originating from the secular parts (the z components) of the first and third terms in the Hamiltonian [equation (1)] and the corresponding EPR transitions. When considering ENDOR, the second term in equation (1), the nuclear Zeeman term, must be taken into account. This leads to the energy levels and the corresponding ENDOR transitions shown in the center of Figure 2.

In principle, the energy levels of the NMR shown on the right in Figure 2 should also be split into two lines with the same splitting constant a . However, this splitting cannot be observed because the NMR lines are broadened by at least two types of time-dependent phenomena associated with the unpaired electrons; first, electronic spin–lattice relaxation with the time constant $T_{1,S}$ and second, electronic exchange with the time constant τ_{ex} . In general, these time constants are sufficiently short to satisfy the following condition

$$T_{1,S} \ll \frac{1}{2\pi a} \quad \text{and/or} \quad \tau_{ex} \ll \frac{1}{2\pi a} \quad (2)$$

Hence one obtains in this case, instead of a splitting, a paramagnetic shift $\Delta B = B_d - B_p$ or $\Delta\nu = \nu_p - \nu_d$.^{6,7} In this

paper we use frequency units rather than magnetic field units since they give a direct measure of the energy differences and since the coupling constant a is identical whether it is measured by EPR or by NMR, while in magnetic field units the ratio of the magnetogyric ratios of the electron and the nucleus must be taken into account.

A paramagnetic shift δ_p termed the isotropic hyperfine contact interaction shift was defined⁶ in analogy to the diamagnetic chemical shift but with the opposite sign, i.e. with a positive sign for a downfield shift and a negative sign for an upfield shift. Since the magnitude of δ_p depends on the Boltzmann factor of the electronic Zeeman energy levels, it is temperature dependent. Its magnitude measured in ppm is given by

$$\delta_p(T) = \frac{B_d - B_p}{B_d} = \frac{a' \hbar \gamma_S^2}{4kT\gamma_I} \quad (3a)$$

$$\delta_p(T) = \frac{\nu_p - \nu_d}{\nu_d} = \frac{a\hbar\gamma_S}{4kT\gamma_I} \quad (3b)$$

where the coupling constant a' is measured in tesla and a is in hertz. For protons at room temperature the result is

$$\delta_p(295 \text{ K}) = a \cdot 26.8 \text{ ppm MHz}^{-1} \quad (3c)$$

Note that with this definition the paramagnetic shift is not measured with respect to any standard, but is measured with respect to the same nucleus in a diamagnetic molecule as similar as possible to the radical.

As $\delta_p(T)$ is proportional to the coupling constant a , the latter can be determined by measuring $\delta_p(T)$ using NMR as well as from the HFS of EPR. At room temperature the coupling constant a_i of the i th nucleus is given by

$$a_i = \frac{4kT\gamma_I}{h\gamma_S} \delta_p(295 \text{ K}) \text{ MHz} \quad (4a)$$

Inserting the constants, one obtains for protons

$$a_i = 3.73 \times 10^{-2} \delta_p(295 \text{ K}) \text{ MHz} \quad (4b)$$

Measuring the coupling constant a by NMR has one additional advantage: while EPR renders only the absolute value of a , $\delta_p(T)$ gives the sign as well. This is particularly valuable for small coupling constants. While in the case of medium or large coupling constants the sign can usually be calculated theoretically with high certainty, this is not so for small coupling constants, the measurement of which is the main domain of NMR.

3 ¹H NMR

The first NMR spectrum of a free radical, namely di-*t*-butyl nitroxide (DBNO), which is a liquid at room temperature, is shown (with TMS as an internal standard) in Figure 3.⁶ The linewidth is found to be $\Delta\nu = 230 \text{ Hz}$ and the shift $\delta_p(295 \text{ K}) = -8.0 \text{ ppm}$ which, following equation (4), give a coupling constant $a_i = -0.298 \text{ MHz}$. Note that in this case $\delta_p(T)$ was

Figure 3 ^1H NMR spectrum of the liquid free radical di-*t*-butyl nitroxide with TMS as internal standard

measured with respect to the internal standard TMS because no diamagnetic molecule of similar structure was available; since the ^1H nuclei in TMS are also in methyl groups, the deviation can be assumed to be rather small. It has been pointed out⁸ that to obtain the correct paramagnetic shift $\delta_p(T)$ for neutral radicals its dependence on the concentration of the paramagnetic species must be measured and extrapolated to zero, because otherwise the varying magnetic susceptibility falsifies the result. This is certainly true when using an external standard. However, when using an internal standard, either a general standard like TMS for ^1H nuclei or an atom in a molecule that is as similar as possible, this effect is compensated for by the fact that the standard is in a medium with the same bulk susceptibility as the radical. In this case, the error when measuring the different concentrations up to a neat liquid radical stays usually below 10%, i.e. it does not exceed the typical solvent effect.

It is obvious that the critical quantity in NMR measurements of paramagnetic species is the linewidth, since this determines both the possible resolution and the sensitivity. For nuclei with spin $I = \frac{1}{2}$ in paramagnetic compounds the linewidth $\Delta\nu$ is proportional to the square of the interaction between the nucleus and the unpaired electron. The two main types of interaction are the scalar contact interaction discussed above and the dipolar interaction. For larger coupling constants a_i , the scalar interaction dominates, but for small a_i values the two can become comparable.

Since the linewidth $\Delta\nu \propto a_i^2$, medium and large values of a_i lead in general to very broad, unobservable NMR absorption lines. However, this broadening effect can be averaged out by sufficiently short time constants. The condition for obtaining narrow lines is much more limiting than equation (2), namely

$$T_{1,S} \ll \frac{1}{2\pi\nu_S} \quad (5)$$

$$\tau_{\text{ex}} \ll \frac{1}{2\pi\nu_S} \quad (6)$$

where ν_S is the Larmor frequency of the electron. Equation (5) and/or equation (6) may be satisfied in favorable cases of certain metal chelate compounds for which very narrow lines have been obtained.

Several attempts can be made to reduce the linewidth to come closer to the condition given in equation (6).

Figure 4 ^1H NMR spectrum of 3,6-dimethyl-1,5-diphenylverdazyl in DBNO

One possibility is to use the liquid free radical DBNO as solvent.⁹ Figure 4 shows as an example the NMR spectrum of 3,6-dimethyl-1,5-diphenylverdazyl in DBNO at a resonance frequency of 90 MHz.⁷ The linewidth varies from about 0.09 MHz to 0.3 MHz, and the different NMR absorption lines are well resolved. The paramagnetic shifts $\delta_p(295\text{ K})$ with respect to the corresponding ^1H resonances of the diamagnetic leucoverdazyl vary between -148 and $+63.5$ ppm. As expected, the linewidth increases with the coupling constant, but even the absorption line of the ^1H atoms in the methyl group in the R^3 position in the central ring, with a linewidth of about 250 kHz, is easily seen although it has a coupling constant as large as $a_i = -5.52$ MHz. One problem with DBNO is that some absorption lines may be hidden below the broad absorption line of DBNO, in this example the line due to the H atom at the C atom in the central ring. In general, the gain in resolution when using DBNO as a solvent is one order of magnitude for larger coupling constants, but much lower for absorption lines of nuclei with small coupling constants.

4 NMR WITH OTHER NUCLEI

Another approach to increasing the resolution is to use ^2H NMR instead of ^1H NMR. The paramagnetic shift of the deuterons (in ppm) is, of course, identical to the shift of the protons. Because of the much smaller magnetogyric ratio of the deuterons one expects a reduction of the shift measured in hertz by a factor of γ_P/γ_D , but a reduction of the linewidth by the square of this quantity $(\gamma_P/\gamma_D)^2$. Hence the net increase in resolution when using deuterons instead of protons should be proportional to $\gamma_P/\gamma_D \approx 6.5$.

The ^2H NMR spectrum of 3-*t*-butyl-1,5-bis(pentadeutero-phenyl)verdazyl in DBNO is reproduced as an example in Figure 5.⁷ The gain in resolution when using ^2H NMR instead of ^1H NMR is found to be about a factor of 2 to 3, but not 6 as expected from theory, considering the Fermi contact interaction only. It follows that the best possible resolution can be obtained using ^2H NMR in DBNO; the maximum gain in resolution $\Delta\nu/\nu$ which is obtained in practice is a factor of about 20.

Figure 5 ^2H NMR spectrum of 3-*t*-butyl-1,5-bis(pentadeuterophenyl)verdazyl in DBNO

The measurement of the coupling constant a_i was extended to ^{13}C NMR.¹⁰ In cases where a_i could be measured by ESR as well, good agreement was found in general. Differences are of the same order (about 10%) as found with ESR in different solvents; the concentration dependence mentioned above also plays a role, since the NMR is usually measured at high concentration ($>2\text{ M}$), while the concentration with the ESR measurements was mostly about 10^{-3} – 10^{-4} M .¹¹ While the coupling constant a_i of the ^1H nucleus is generally mainly determined by the spin density at the atom to which the ^1H is bound (with some geometrical effects), ^{13}C NMR measurements of a series of nitroxide radicals showed that the coupling constants a_i depend in a more complex manner on the polarization of the electrons in the nitrogen–carbon bond and on the carbon–carbon bonds, as well as on geometrical effects.¹¹ The situation is even more complicated with aromatic fluoro compounds where the spin polarization between the 2p orbital of the fluorine and the spin in the 2p orbital of the adjacent carbon atom has to be considered. In favorable cases the sign and magnitude of the fluorine coupling could be obtained.¹²

5 NMR OF RADICAL IONS

A somewhat different situation is encountered when measuring the NMR of radical ions in solution. In general, in the solution both neutral molecules M and the corresponding negative radical ions M^- will be present. In this case there is an electron transfer reaction between these two species, which may be symbolized by¹³

Here the paramagnetic shift $\delta_p(T)$ of a nucleus in the molecule is not given directly by equation (3), but the fraction f_p

of paramagnetic radicals in the solution must be taken into account; this is given by

$$f_p = \text{M}^- / (\text{M} + \text{M}^-) \quad (8)$$

Hence the paramagnetic shift $\delta'_p(T)$ becomes

$$\delta'_p(T) = f_p \delta_p(T) \quad (9)$$

Since the measured quantity in this case is $\delta'_p(T)$, in equation (4), $\delta_p(T)$ must be replaced by $\delta_p(T)/f_p$ in order to obtain the coupling constant a_i . The fraction f_p can be determined from the solvent shift due to the change in the susceptibility of the solution as a function of the reduction of the molecule M .¹³

It was stated above that measurement of the coupling constant a_i of a nucleus within a neutral free radical by NMR is usually restricted to small coupling constants. However, in the case of radical ions the chemical exchange with the time constant $\tau_{\text{ex}}^{\text{ch}}$ can be so fast that it approaches the much stricter conditions of equations (5) and (6); it was estimated to be of the order of $\tau_{\text{ex}}^{\text{ch}} \simeq 10^{-11}$.¹⁴ This is illustrated by the example of biphenyl in diglyme.

Figure 6 shows the ^1H NMR spectrum of biphenyl in diglyme. The ^1H NMR line of the *meta* protons is much sharper and shifted downfield, as would be expected from the negative spin density at the *meta* carbon atom in biphenyl, as opposed to the much broader lines of the *ortho*- and *para*- ^1H atoms. The paramagnetic shift $\delta_p(T)$ of the *ortho*- and *meta*- ^1H atoms is plotted in Figure 7¹⁴ as a function of the solvent shift $\delta_s(T)$ in diglyme when the biphenyl is gradually reduced with sodium.

Over the past 20 years the coupling constants between ^1H and ^2H nuclei and the unpaired electron spins have been measured in many such chemical exchange systems. In the case of ion radicals, even the coupling between the negative ion radicals and the alkali metal counterions (^6Li , ^{23}Na , ^{39}K , etc.) could be measured from the NMR of the alkali metals and the solvent, temperature and concentration dependence could be studied.¹⁵ For more information on hyperfine interaction in NMR, the reader is referred to a series of review articles on the subject which cover the period from 1972 until 1990.¹⁶

Figure 6 ^1H NMR spectrum at room temperature of a completely reduced 1 M solution of biphenyl in diglyme, with sodium as the reducing agent. S, solvent peak. All the peaks were measured with different rf power, gain, and modulation

Figure 7 Contact shift δ_c at room temperature of *ortho*- ^1H and *meta*- ^1H of biphenyl as a function of the solvent shift δ_s for a solution of diglyme (concentration 1 M) gradually reduced with sodium

1 INTRODUCTION

NMR has proven to be of great utility in the study of paramagnetic proteins. Although the presence of the paramagnetic center creates inherent difficulties in obtaining structural information from nearby residues, numerous solution structures now exist for certain classes of paramagnetic proteins.^{1–3} In addition, the interactions between the unpaired electron and surrounding nuclei create new effects that provide sensitive probes of the electronic and geometric structure of the paramagnetic center. Traditionally, it has been very difficult to obtain quantitative information from these electron–nuclear interactions, but with the advent of reliable, high-level computational techniques and the development of new NMR methodologies, this has begun to change. In coupled systems, a vector coupling model has been of great utility in providing a qualitative picture. In this review, we focus exclusively on FeS proteins, which have been extensively studied by NMR, and although they pose some of the greatest challenges, they have yielded some of the most satisfying agreement between theory and experiment.

2 ELECTRON–NUCLEAR INTERACTIONS IN MONONUCLEAR SYSTEMS

Paramagnetic proteins containing a single transition metal site represent the simplest case for the study of electron–nuclear interactions. Even in these systems, however, the analysis of the resulting effects can be quite complex.

2.1 Theory

We discuss here three types of electron–nuclear interactions: hyperfine shifts,^{4,5} paramagnetic relaxation,^{4–6} and residual dipolar couplings.^{7,8} Electron–nuclear interactions provide an additional contribution to the chemical shift, called

the hyperfine shift. This frequently results in peaks appearing far outside the region typical for diamagnetic shifts. Electron–nuclear interactions also give rise to additional NMR relaxation mechanisms that can broaden peaks and make them inaccessible to detection by traditional multidimensional NMR approaches. Residual dipolar couplings appear when a molecule becomes partially ordered with respect to the external magnetic field of the NMR experiment. A protein with an anisotropic magnetic susceptibility tensor will become ordered in a strong magnetic field; and this ordering will show up as changes in couplings between the nuclei of nearby magnetically active atoms. All three effects, hyperfine shifts, paramagnetic relaxation, and residual dipolar couplings, can be rich sources of information about protein structure and the properties of the metal site.

Hyperfine shifts arise from the sum of two distinct interactions: the Fermi contact shift, δ_{con} , and the electron–nuclear dipolar or pseudocontact shift, δ_{pc} . The observed chemical shift, δ_{tot} , is the sum of these two plus the diamagnetic chemical shift, δ_{dia} :

$$\delta_{\text{tot}} = \delta_{\text{con}} + \delta_{\text{pc}} + \delta_{\text{dia}} \quad (1)$$

The Fermi contact shift arises from delocalization of unpaired electron density onto ligand orbitals. Only unpaired spin density at the nucleus contributes to the Fermi contact coupling. The equation for the Fermi contact shift in ppm is:

$$\delta_{\text{con}} = 10^6 \left(\frac{\Delta\nu}{\nu_0} \right)^{\text{con}} = -10^6 \frac{A}{\hbar\gamma_N B_0} \langle S_z \rangle \quad (2)$$

where A is the isotropic hyperfine constant in Joules and $\langle S_z \rangle$ is the expectation value of S_z . (Note that hyperfine coupling is usually reported as $A/\hbar$, which has units of hertz.) In the absence of first-order orbital angular momentum or zero-field splitting (ZFS), this simplifies to:

$$\delta_{\text{con}} = 10^6 \left(\frac{\Delta\nu}{\nu_0} \right)^{\text{con}} = 10^6 \left(\frac{A}{\hbar} \right) \frac{g\mu_B S(S+1)}{3\gamma_N kT} \quad (3)$$

where g is the average molecular electron g -value (frequently assumed to be $\sim g_e$, the free electron g -value). This isotropic hyperfine coupling constant can in turn be related to the unpaired spin density at the nucleus:

$$A = \frac{\mu_0}{3S} \hbar\gamma_N g\mu_B \sum_i [|\psi_i^-(0)|^2 - |\psi_i^+(0)|^2] \quad (4)$$

where $|\psi_i^-(0)|^2$ and $|\psi_i^+(0)|^2$ are the negative and positive spin density at the nucleus of the i th molecular orbital.

The pseudocontact shift is the other contribution to the hyperfine shift. The electron magnetic moment is anisotropic as a result of coupling with the orbital angular momentum, and thus it does not average to zero with molecular tumbling. This yields an isotropic shift that is dependent upon the electron–nuclear distance. The ‘point-dipole’ approximation is usually invoked, in which all of the unpaired electron density is localized at the metal center. This yields:

$$\begin{aligned} \delta_{\text{pc}} &= 10^6 \left(\frac{\Delta\nu}{\nu_0} \right)^{\text{pc}} = 10^6 \frac{1}{8\pi r^3} \left[(3\cos^2\theta - 1) \right. \\ &\quad \times \left(\frac{2}{3}\chi_{zz} - \frac{1}{3}\chi_{xx} - \frac{1}{3}\chi_{yy} \right) \\ &\quad \left. + \sin^2\theta \cos 2\phi (\chi_{xx} - \chi_{yy}) \right] \end{aligned} \quad (5)$$

where r is the electron–nuclear distance, χ_{zz} , χ_{xx} , and χ_{yy} are the principle components of the magnetic susceptibility tensor, and θ and ϕ are the angles formed by r and the molecular z axis and the projection of r in the xy plane with the molecular x axis. Again, assuming no ZFS, this simplifies to:

$$\begin{aligned} \delta_{pc} = 10^6 \left(\frac{\Delta\nu}{\nu_0} \right)^{pc} = 10^6 \frac{\mu_0 \mu_B^2 S(S+1)}{4\pi 18kTr^3} \\ \times [2g_{zz}^2 - (g_{xx}^2 + g_{yy}^2)](3\cos^2\theta - 1) \\ + 3(g_{xx}^2 - g_{yy}^2)\sin^2\theta\cos 2\phi \end{aligned} \quad (6)$$

In analyzing hyperfine shifts, a first step is the separation of the Fermi contact and pseudocontact contributions. As seen in equation (5), the pseudocontact shift is related to the magnetic susceptibility anisotropy. In FeS systems at room temperature, this is small, and for nuclei that are only a few bonds away from the Fe, the Fermi contact term will overwhelmingly dominate. For nuclei close in space but many bonds away from the Fe, the pseudocontact shift will dominate, and can in principle provide useful distance information.

As in the case of hyperfine shifts, the paramagnetic contribution to the nuclear T_1 and T_2 relaxation rates arise from several different contributions: electron–nuclear dipolar, contact, and Curie spin. The equations for these are

$$\begin{aligned} T_{1dip}^{-1} = \frac{2}{15} \left(\frac{\mu_0}{4\pi} \right)^2 \frac{\gamma_N^2 g^2 \mu_B^2 S(S+1)}{r^6} \\ \times \left[\frac{\tau_c}{1 + (\omega_I - \omega_S)^2 \tau_c^2} + \frac{3\tau_c}{1 + \omega_I^2 \tau_c^2} \right. \\ \left. + \frac{6\tau_c}{1 + (\omega_I + \omega_S)^2 \tau_c^2} \right] \end{aligned} \quad (7)$$

$$T_{1con}^{-1} = \frac{2}{3} \left(\frac{A}{h} \right)^2 S(S+1) \frac{\tau_e}{1 + (\omega_I - \omega_S)^2 \tau_e^2} \quad (8)$$

$$\begin{aligned} T_{2dip}^{-1} = \frac{1}{15} \left(\frac{\mu_0}{4\pi} \right)^2 \frac{\gamma_N^2 g^2 \mu_B^2 S(S+1)}{r^6} \\ \times \left[4\tau_c + \frac{\tau_c}{1 + (\omega_I - \omega_S)^2 \tau_c^2} + \frac{3\tau_c}{1 + \omega_I^2 \tau_c^2} \right. \\ \left. + \frac{6\tau_c}{1 + (\omega_I + \omega_S)^2 \tau_c^2} + \frac{6\tau_c}{1 + \omega_S^2 \tau_c^2} \right] \end{aligned} \quad (9)$$

$$T_{2con}^{-1} = \frac{1}{3} \left(\frac{A}{h} \right)^2 S(S+1) \left[\tau_e + \frac{\tau_e}{1 + (\omega_I - \omega_S)^2 \tau_e^2} \right] \quad (10)$$

$$T_{2curie}^{-1} = \frac{1}{5} \left(\frac{\mu_0}{4\pi} \right)^2 \frac{\omega_I^2 g^4 \mu_B^4 S^2(S+1)^2}{(3kT)^2 r^6} \left[4\tau_r + \frac{3\tau_r}{1 + \omega_I \tau_r^2} \right] \quad (11)$$

where ω_I and ω_S are the nuclear and electron Larmor precession frequencies, τ_r is the rotational correlation time, τ_e is the electronic relaxation rate, and τ_c is the total correlation time, given as:

$$\tau_c^{-1} = \tau_r^{-1} + \tau_e^{-1} \quad (12)$$

In these equations, several simplifying assumptions have again been made: the point-dipole approximation holds, g is isotropic, and ZFS is negligible. More complex equations have

been derived that include g anisotropy and ZFS.⁶ Of these simplifications, the point-dipole approximation generally is the one that fails in a quantitative analysis of relaxation rates. This is especially the case in Fe–S proteins, where the Fe is highly covalent and the electron density is delocalized significantly out onto the ligands. This is sometimes referred to as the ‘ligand-centered’ dipolar contribution to the relaxation rate, and attempts have been made to account for it.⁹ In the high-temperature limit, the electronic transverse and longitudinal relaxation rates (T_{1e} , T_{2e}) are essentially equal, and this can be taken as the value of τ_e . The contributions to τ_e are numerous, and in general, prevent its independent determination. Nonetheless, τ_e is assumed to be $\sim 10^{-10}$ – 10^{-11} s for mononuclear high-spin (h.s.) Fe^{3+} and $\sim 10^{-11}$ – 10^{-12} s for mononuclear h.s. Fe^{2+} .⁶ Curie spin relaxation, which arises from the interaction of the nuclear magnetic moment with the large static magnetic moment provided by the unpaired electrons of the metal center, can be by far the dominant contribution to T_2 , especially at high fields, for proteins with a high-spin metal site (e.g., h.s. Fe^{3+}) and/or high molecular weight. The Curie spin contribution to T_1 is very small and can be ignored. Because of the strong dependence of the relaxation rate on the nuclear magnetogyric ratio, γ , hyperfine signals from nuclei with a low γ (e.g., ^{15}N and 2H) are more readily observed than signals from nuclei with high γ (1H). Thus, one strategy for the study of paramagnetic systems is to collect 1D ^{15}N and 2H NMR data on isotopically labeled samples. Note that the chemical shifts of 1H and 2H are essentially equivalent.

The third type of electron–nuclear interaction is residual dipolar coupling. In solution-state NMR, rapid molecular tumbling normally averages out dipolar couplings. However, in a system with a sufficiently anisotropic magnetic susceptibility tensor, a high magnetic field can lead to partial ordering of the molecules. Because the effect is proportional to the square of the magnetic field, the dipolar couplings can be extracted from analysis of one-bond 1H – X couplings at two different fields. The magnitude of $^1D_{HX}$ is related to the magnetic susceptibility anisotropy:

$$\begin{aligned} ^1D_{HX} = \frac{-\gamma_X \gamma_H B_o^2}{40kT\pi^2 r^3} \left[(3\cos^2\theta - 1) \left(\chi_{zz} - \frac{1}{2}\chi_{xx} - \frac{1}{2}\chi_{yy} \right) \right. \\ \left. + \frac{3}{2}\sin^2\theta\cos 2\phi(\chi_{xx} - \chi_{yy}) \right] \end{aligned} \quad (13)$$

Note that the form of this equation is very similar to that for the pseudocontact shift (equation 5); however, residual dipolar couplings can be measured directly, whereas pseudocontact shifts must be deconvoluted from the Fermi contact and diamagnetic components of the observed chemical shift.

2.2 Applications to Fe(Cys)₄ Proteins

The most extensive study of hyperfine shifts in Fe(Cys)₄ proteins is for *Clostridium pasteurianum* rubredoxin (CpRd). Extensive and definitive assignments were obtained for the H and N atoms of the ligating Cys residues and eight nearby amide N atoms in both oxidation states through the use of selective 2H and ^{15}N labeling, including chirally deuterated Cys and single-site labeling (Figure 1(a)–(f), Table 1).^{10–13} Also, the Cys C $^\beta$ resonances from reduced CpRd were identified by selective labeling (Figure 1(g), Table 1).¹²

For CpRd, Fermi contact shifts were calculated with hybrid density functional theory (HDFT) using 104-atom models¹⁴ derived from three published crystal structures of oxidized CpRd at 1.1–1.2 Å resolution.^{15–17} Extremely good agreement was obtained between the calculated Fermi contact shifts and all of the observed ^2H and ^{15}N hyperfine shifts for all three models (in one model, a correction to the placement of the amide H atoms was required). The pseudocontact shift was small enough that it could safely be ignored. The agreement between calculated and experimental hyperfine shifts was excellent. All assignments achieved by selective labeling were confirmed in the calculations, and the calculations allowed definitive sequence-specific assignments for nearly all the remaining hyperfine-shifted ^2H and ^{15}N signals. These results validate the approach and indicate that HDFT calculations are a powerful tool for obtaining a quantitative understanding of hyperfine shifts and electronic structure of metalloproteins.

In the case of CpRd, this approach demonstrated the importance of hydrogen bonding to the ligating Cys S^γ atoms. In CpRd, six backbone amides donate H-bonds to the Cys S^γ atoms: residues Val8, Cys9, Tyr11, Leu41, Cys42, and Val44. In particular, the N atoms of Tyr11 and Val44 exhibit large hyperfine shifts but are eight covalent bonds from the

Fe. The conclusion, corroborated by the HDFT calculations, is that H-bonds are capable of delocalizing spin density, a feature that may be important in the electron transfer function of these systems. The calculations further showed an inverse correlation between the magnitude of the hyperfine shift and $\text{H}\cdots\text{S}^\gamma$ distance. (Signals from the ^{15}N atoms of the ligating Cys residues have a separate intercept because they also derive appreciable unpaired spin density through covalent bonds.) Another effect of spin delocalization through H-bonds is the large (≥ 8 ppm) negative one-bond $^1\text{H}/^2\text{H}$ isotope effects on the chemical shifts of the Val8, Tyr11, Leu41, and Val44 N atoms (Table 1).¹³ Again, HDFT calculations were able to quantitatively account for this isotope effect.¹³ Recent ^{15}N NMR data¹⁸ on a mutant of CpRd with a very different N– S^γ length for one of the H-bonds as determined by X-ray crystallography¹⁹ are consistent with the correlation between H-bond length, spin density, and in turn, hyperfine shift. The calculations also helped interpret the ^2H , ^{15}N , and ^{13}C chemical shifts for reduced CpRb.¹⁴ Since only coordinates for oxidized CpRd were available, the correlation between the experimental and calculated chemical shifts were not as good, and therefore the residue-specific assignments are only preliminary. Subsequent calculations based on the recently

published X-ray structure for reduced CpRd²⁰ are yielding improved agreement with experiment and hence more insight into the electronic structure.²¹

HDFT calculations were extended to obtain a quantitative understanding of the ¹⁵N *T*₁ relaxation rates in oxidized CpRd.²² In this system, the contact contribution is small even for the most strongly hyperfine-shifted resonances and the *T*₁ rates are dominated by electron–nuclear dipolar relaxation. However, given that the unpaired spin density in this system is known to be highly delocalized, the point-dipole approximation is a poor model. This was accounted for by replacing the *r*^{−6} distance dependence in equation (7) with an effective reciprocal distance, *r*_{eff}^{−6}:

$$r_{\text{eff}}^{-6} = \frac{1}{4} \left[\frac{1}{3} (\langle q_{xx} \rangle_{\text{spin}} - \langle q_{yy} \rangle_{\text{spin}})^2 + \langle q_{xx} \rangle_{\text{spin}}^2 + \frac{4}{3} (\langle q_{xy} \rangle_{\text{spin}}^2 + \langle q_{xz} \rangle_{\text{spin}}^2 + \langle q_{yz} \rangle_{\text{spin}}^2) \right] \quad (14)$$

In equation (14), the $\langle q_{\alpha\beta} \rangle_{\text{spin}}$ terms are the matrix elements of the spin-differential field gradient tensor:

$$\langle q_{\alpha\beta} \rangle_{\text{spin}} = \sum_{st} D_{st} \langle s | \hat{q} | t \rangle \quad (15)$$

where *D*_{st} is the normalized, spin-only density matrix and *q*_{αβ} is the electric field gradient operator:

$$\hat{q}_{\alpha\beta} = \frac{3r_{\alpha}r_{\beta} - \delta_{\alpha\beta}r^2}{r^5} \quad (16)$$

This approach provided excellent agreement between experimental and calculated ¹⁵N *T*₁ rates, whereas the point-dipole model failed for nuclei closer than 7 Å. A comparison of *r*_{eff} with the crystallographic distance demonstrates this (Figure 2). These calculations yielded a *τ*_c of $\sim 4 \times 10^{-10}$ s. In this system, *τ*_c $\approx$ *τ*_e, and this value for *τ*_e is typical for Fe³⁺.

The magnetic field-dependence of one-bond ¹H–¹⁵N and ¹H^α–¹³C^α couplings were measured in order to determine the residual dipolar couplings in oxidized and reduced CpRd.⁸ These, in combination with the crystallographic data, were used to obtain the magnitude and orientation of the magnetic susceptibility anisotropy, Δ*χ*_{ax} and Δ*χ*_{rh} (Figure 3). By subtracting the calculated diamagnetic contribution from the protein, Δ*χ*_{ax} and Δ*χ*_{rh} for the metal center can be determined: 7.93×10^{-28} and 3.24×10^{-28} cm³ molecule^{−1} for oxidized and 22.3×10^{-28} and 10.5×10^{-28} cm³ molecule^{−1} for reduced CpRd, respectively (Table 2).

These values, in turn, can be compared with ZFS parameters and *g*-values previously obtained by other methods for rubredoxins and Fe(SR)₄ model complexes. Since the magnetic susceptibility anisotropies were measured at 10 °C, the values are very sensitive to small differences in both the **D**-

Figure 2 Plot of *r*_{xtal} − *r*_{eff} versus *r*_{xtal}, where *r*_{xtal} is the measured distance between individual ¹⁵N nuclei and the Fe atom in the 4RXN crystal structure and where *r*_{eff} is the effective distance calculated from the wave function using the spin-differential field gradient tensor method. Black circles represent ¹⁵N nuclei that give rise to hyperfine-shifted resonances and open circles represent the ‘diamagnetic’ ¹⁵N nuclei. The horizontal line is drawn at the zero of the abscissa. The inset plot shows an expansion of the ordinate for nuclei that are close to the metal center. Reproduced with permission from Ref.²² Copyright 1998 American Chemical Society

Figure 3 Structural representation of magnetic susceptibility anisotropies. A ribbon diagram of the structure of CpRd is shown, including the atoms of the $\text{Fe}(\text{Cys})_4$ center. Vectors originating at the Fe indicate the magnitudes and show the orientations of the $\Delta\chi_{\text{ax}}$ and $\Delta\chi_{\text{rh}}$ terms obtained from fits to the 5RXN structure of dipolar splittings from oxidized and reduced CpRd. The diamagnetic $\Delta\chi_{\text{ax}}$ and $\Delta\chi_{\text{rh}}$ values calculated for 5RXN are also shown. Reproduced with permission from Ref.⁸ Copyright 1998 American Chemical Society

and $\mathbf{g}$ -tensors and their relative orientation; thus, they can only be compared to the previous data in general terms.

ZFS parameters have been obtained for oxidized CpRd from Mössbauer spectroscopy^{23,24} and for oxidized *Pseudomonas oleovorans* rubredoxin from variable-temperature X-band EPR spectroscopy²⁵ (Table 2). Both approaches yielded a D that is small and positive, consistent with an approximately D_{2d} geometry; in these calculations, g was assumed to be isotropic and ~ 2.0 . The values of D , E , and g obtained from EPR can be used to calculate $\Delta\chi_{\text{ax}}$ and $\Delta\chi_{\text{rh}}$, which yields the qualitatively consistent values of 7.27×10^{-28} and $4.15 \times 10^{-28} \text{ cm}^3 \text{ molecule}^{-1}$, respectively. Agreement with the NMR-derived values can be improved substantially by assuming a g -anisotropy of 0.004; this small value is reasonable on the basis of data for a $\text{Fe}^{3+}(\text{SR})_4$ model complex.²⁶

ZFS parameters have been obtained for reduced CpRd from Mössbauer spectroscopy (Table 2)²³ and for a model complex, $[\text{Fe}(\text{SPh})_4]^{2-}$, from Mössbauer,²⁷ high-frequency EPR (HFEPR),²⁸ and far-infrared (FIR) absorption spectroscopies.²⁹ In the latter system, the ZFS parameters obtained from HFEPR and FIR were in agreement and significantly smaller than from those obtained from Mössbauer. Results from the model system were used to derive ZFS parameters for CpRd (Table 2).²⁸

In all cases, g -values were inferred from expressions derived from second-order perturbation theory (Table 2).³⁰ $\Delta\chi_{\text{ax}}$ and $\Delta\chi_{\text{rh}}$ values calculated from Mössbauer-derived values of D , E , and g are approximately twice the experimental values determined by NMR, whereas those derived from HFEPR (22.5×10^{-28} and $13.4 \times 10^{-28} \text{ cm}^3 \text{ molecule}^{-1}$, respectively) are in good agreement. Again, small changes in the g -anisotropy would account for the remaining difference.

Once the magnitude and orientation of the magnetic susceptibility anisotropy were determined for oxidized and reduced CpRd, these data could be used to estimate the pseudocontact shifts for nuclei $>11 \text{ Å}$ from the Fe center. From this it was found that pseudocontact shifts entirely accounted for the observed chemical shift differences between the oxidized and reduced states for the diamagnetic resonances. This, in turn, indicated that the structure of the protein 7 Å or more from the Fe remains the same in the two redox states.

3 EXCHANGE COUPLING AND ITS INFLUENCE ON ELECTRON–NUCLEAR INTERACTIONS

Electron–nuclear interactions in exchange coupled multinuclear systems are considerably more complicated than those in simple single-metal site systems. As with simpler systems, NMR data can be used to evaluate theoretical models describing the paramagnetic center. In particular, the nature of exchange coupling in the mixed-valence states of these clusters has been a topic of great interest. The types of exchange-coupled FeS clusters that have been studied by NMR spectroscopy and their different formal redox states are listed in Table 3. An extensive list of NMR results on different FeS proteins is provided in Table 4.

In this section, we present the theory of how exchange coupling impacts hyperfine shifts and paramagnetic relaxation. We then show how the vector coupling model of hyperfine shifts has been applied to representative FeS clusters and the insight this has provided.

3.1 Theory

In a coupled system, the exchange coupling can be described by the phenomenological spin Hamiltonian:

$$\mathcal{H} = \sum_{i < j} -2J_{ij} \mathbf{S}_i \cdot \mathbf{S}_j \quad (17)$$

where J is the isotropic or Heisenberg exchange coupling constant and $\mathbf{S}_i$ and $\mathbf{S}_j$ are the local spin operators for each metal site. For a system with two metal centers, such as $[\text{2Fe–2S}]^{2+}$, this yields a set of levels or “spin ladder” for the total spin S , in which S ranges from $|\mathbf{S}_1 + \mathbf{S}_2|$ to $|\mathbf{S}_1 - \mathbf{S}_2|$, the relative energies of which are given by:

$$E(S) = -JS(S+1) \quad (18)$$

J can be positive (ferromagnetic coupling) or negative (antiferromagnetic coupling). In FeS clusters J is always negative. In mixed-valence systems, such as $[\text{2Fe–2S}]^+$, the extra electron can be on either Fe; this doubles the number of total spin states. Consideration of this effect, called double

Table 2 Comparison of the magnetic susceptibility anisotropy of oxidized and reduced rubredoxin obtained from NMR with the ZFS parameters and g -values obtained from Mössbauer and EPR and the magnetic susceptibility anisotropy calculated from these

exchange or spin-dependent delocalization, yields the following equation for the energies of the total spin states are now defined by:

$$E(S) = -JS(S+1) \pm B\left(S + \frac{1}{2}\right) \quad (19)$$

where B is the double exchange term. The interplay between J and B determines the ground state (g.s.) of the system. Two additional effects must be considered: static and dynamic asymmetry. Static asymmetry arises from differences in the coordination geometry, H-bonding, and protein electrostatics at the two Fe sites that cause the extra electron to be preferentially localized on one side. Dynamic asymmetry, or vibronic coupling, arises from the change in geometry upon transferring the extra electron from one side to the other. The magnitude of this nuclear distortion defines the height of the barrier to electron transfer between the two sides. Thus, in the limit of large B and small vibronic coupling, there is no barrier to intersite electron transfer and the system is said to be completely valence-delocalized. For example, a valence-delocalized [2Fe-2S]⁺ cluster would be described as 2Fe^{2.5+}. Together, static asymmetry and vibronic coupling counteract the effect of double exchange. In the limit where these effects are large relative to B , the system is valence-localized and can be described by equations (17) and (18),

where J is replaced by a J_{eff} , which is the Heisenberg J plus a correction factor to account for B , static asymmetry, and vibronic coupling. For systems of higher nuclearity, the exchange coupling can be described by decomposing the system into subunits and first considering the coupling within the subunits, and then the coupling between the subunits. For a more detailed account of exchange coupling, see Ref.³¹ and references therein.

In an exchange coupled system, the Fermi contact shift can still be described by equation (2), but now one must calculate the Fermi contact shift for each total spin state, each of which will have a different isotropic hyperfine coupling constant, A_i , and sum over the Boltzmann population of the total spin states. The difficulty lies in determining each A_i ; however, this can be accomplished readily because the hyperfine coupling constant for each total spin state S , in turn, can be related to the intrinsic hyperfine coupling constant for each metal site, A_j . Thus, equation (2) may be rewritten as:³²

$$\delta_{\text{con}} = 10^6 \left(\frac{\Delta\nu}{\nu_0} \right)^{\text{con}} = -10^6 \frac{1}{\hbar\gamma_N B_0} \sum_i \sum_j A_j C_{ji} \langle S_z \rangle_i \quad (20)$$

where C_{ji} are spin projection coefficients for each metal site j for each total spin state i . These are derived from the

Wigner–Eckart theorem and vector coupling.³³ For a binuclear system, C_1 is given by^{31–34}

$$C_1 = \frac{S(S+1) + S_1(S_1+1) - S_2(S_2+1)}{2S(S+1)} \quad (21)$$

where S is the total spin and S_1 and S_2 are the spin states of each metal site. C_2 is given by simply reversing the indices in equation (21). This can be easily extended to systems of higher nuclearity by use of a chain rule.³⁴ Consider a tetranuclear system that can be divided into two subunits of spin S_p and S_q . From equation (21), spin projection coefficients C_1^p and C_2^p can be calculated by replacing S with S_p and C_p by replacing S_1 and S_2 with S_p and S_q . Coefficients projecting out the spin onto the total spin state are then:

$$C_1 = C_1^p C_p \quad (22)$$

Note also that the spin projection coefficients for each total spin state always sum to one. Considering an explicit expression for the spin expectation value in equation (20) yields:

$$\begin{aligned} \delta_{\text{con}} &= 10^6 \left(\frac{\Delta\nu}{\nu_0} \right)^{\text{con}} = -10^6 \frac{g\beta}{\hbar\gamma_N 3kT} \\ &\times \sum_j \frac{A_j \sum_i C_{ji} S(S+1)(2S+1) \exp(-E_S/kT)}{\sum_i (2S+1) \exp(-E_S/kT)} \quad (23) \end{aligned}$$

Application of equation (23) is still difficult, and as shown below, has only been attempted qualitatively.

Paramagnetic relaxation can be analyzed by a treatment similar to equations (20) and (23). For example, the point-dipole approximation of the electron–nuclear dipolar contribution to T_1 may be written as:³²

$$\begin{aligned} T_{1j}^{-1} &= \frac{2}{15} \left(\frac{\mu_0}{4\pi} \right)^2 \frac{\gamma_N^2 g^2 \beta^2}{r_j^2} \frac{\sum_i C_{ji}^2 S(S+1)(2S+1) \exp(-E_S/kT)}{\sum_i (2S+1) \exp(-E_S/kT)} \\ &\times \left[\frac{\tau_c}{1 + (\omega_I - \omega_S)^2 \tau_c^2} + \frac{3\tau_c}{1 + \omega_I^2 \tau_c^2} + \frac{6\tau_c}{1 + (\omega_I + \omega_S)^2 \tau_c^2} \right] \quad (24) \end{aligned}$$

where T_{1j} is the dipolar relaxation from metal site j , r_j is the distance to that metal site, and τ_c is given as in equation (12). This is then summed over all metal sites. Similar equations may be derived for the other types of paramagnetic relaxation. The issue arises as to what value to use for the electronic relaxation rate. In the limit of strong exchange coupling, where the coupling frequency is large relative to the electronic relaxation rates for the uncoupled spins (τ_{ej}) but small relative to the electronic correlation time (τ_{vj}) the electronic relaxation rate is the same for all metal sites.³⁵

$$\frac{|J|}{\hbar} \gg \tau_{ej}^{-1} \quad (25)$$

$$\frac{|J|}{\hbar} \ll \tau_{vj}^{-1} \quad (26)$$

This case holds for FeS clusters. See⁶ and³⁵ for more details. Although detailed analyses of nuclear and electronic relaxation in coupled systems are few, equation (24) has been of great utility in providing distance constraints for solution structure determination.^{36–39}

3.2 Applications to Fe–S Cluster Proteins

3.2.1 [2Fe–2S] Clusters

[2Fe–2S] proteins can be divided into two classes: 2Fe ferredoxins (Fds), in which each Fe is ligated by two Cys residues, and Rieske proteins, in which one Fe is ligated by two Cys and the other by two His.^{40,41} The 2Fe Fds can be subdivided further into several types, two of which have been studied by NMR: plant-type and hydroxylase-type. In the oxidized state of both types, the ¹H hyperfine-shifted resonances are extremely broad and unresolved. The Cys H^β and H^α protons have been assigned by selective labeling, as have the Cys C^β and N resonances (Table 5).^{42–44} All the

hyperfine resonances move to higher frequency with increasing temperature or exhibit little temperature-dependence.

The electronic structure of the reduced state is very highly conserved among plant-type 2Fe Fds, based upon EPR, Mössbauer, and other studies.^{45–48} Similar studies on reduced hydroxylase-type 2Fe Fds indicate that they, too, have a very highly conserved spectral signature that differs considerably from that of plant-type Fds,^{45–48} despite their very similar geometries in the oxidized state (cf., e.g.,⁴⁹ and⁵⁰). In the plant-type Fds, the hyperfine resonances are far narrower in the reduced state than in the oxidized state, thus facilitating their assignment. In reduced *Anabaena* PCC7120 vegetative Fd, extensive assignments were obtained for the Cys H^β, H^α, C^β, and N resonances through selective labeling, 2D NOESY (tailored for fast-relaxing resonances), 2D ¹H{¹³C} HSQC, and 1D heteronuclear decoupling experiments (Table 5).^{43,44,51} The ¹H NMR spectrum is shown in Figure 4(a).

One very important conclusion from these studies is that the [2Fe–2S]⁺ cluster is valence trapped even at room temperature on the NMR timescale and that the electron resides entirely on the Fe ligated to Cys 41 and 46.⁵² This is consistent with, although not necessarily predicted by, the large negative

value of J_{eff} that has been measured by magnetic susceptibility and temperature-dependent EPR. Less work has been done on reduced hydroxylase-type Fds. Partial assignments derived from selective ^2H labeling are available for human Fd: H^β resonances occur at 103, 80, -10 , and -15 ppm, and H^α resonances at 37 and 13 ppm.⁴⁴ As in the case of plant-type Fds, these data indicate valence-trapping.

A theoretical model was developed by Dunham⁵³ and later extended by Banci and Bertini^{32,54} by use of equation (23) to explain the sign, magnitude, and temperature dependence of the chemical shifts of the ^1H hyperfine resonances in reduced Fds. In this model, the intrinsic hyperfine coupling constants

for Cys H^β and H^α protons were assumed to be 1.0 and 0.1 MHz, respectively, and to be only coupled to the closer of the two Fe sites; thus, J_{eff} becomes the only scalable parameter. From magnetic susceptibility and temperature-dependent EPR, J_{eff} is approximately -100 cm^{-1} in plant-type Fds^{46,55–59} and -250 cm^{-1} in hydroxylase Fds.^{45,46,59} Remarkably good agreement with this model is obtained for the ^1H hyperfine data on plant-type Fds, but only if J_{eff} is assumed to be half the experimental value (Figure 5(b)).

In this case, at room temperature, the H^β and H^α protons on the Fe^{3+} side are predicted to be at 123 and 17 ppm, respectively, and to shift to lower frequency with increasing

temperature, and the H^β and H^α protons on the Fe^{2+} side are predicted to be at 26 and 7 ppm, respectively, and to shift to higher frequency with increasing temperature. Qualitative agreement is found for the hydroxylase-type Fds using the experimental value for J_{eff} : the H^β and H^α protons on the Fe^{3+} side are predicted to be at 67 and 11 ppm, respectively, and to shift to lower frequency with increasing temperature, and the H^β and H^α protons on the Fe^{2+} side are predicted to be at -29 and 1.5 ppm, respectively, and to shift to higher frequency with increasing temperature (Figure 5(b)). The model breaks down when comparing temperature dependence of the ^{15}N and ^{13}C hyperfine shifts, where there is not a clear pattern of two resonances shifting to higher frequency and two to lower frequency. A similar approach can be used for understanding the hyperfine shifts in $[2Fe-2S]^{2+}$ clusters. Since in this case the g.s. is $S = 0$, only thermal population of paramagnetic excited states yields hyperfine shifts. Here J is large (-175 cm^{-1}),⁴⁶ so all of the resonances shift to higher frequency with increasing temperature

as the population of paramagnetic excited states increases (Figure 5(a), solid lines).⁵⁴ Overall, the success of the vector coupling model in qualitatively explaining hyperfine shifts in $[2Fe-2S]$ clusters justifies its use in more complex systems.

Among the Rieske proteins, the one from the toluene-4 monooxygenase system of *P. mendocina* (TMOC) is the best characterized by NMR. In the reduced state, the 1H spectrum exhibits five resonances at high frequency (Figure 4(b), Table 5) that have been assigned as Cys H^β and His $H^{\epsilon 1}$ protons based upon selective 2H labeling.⁶⁰ This study also provided a thorough examination of the ^{15}N hyperfine shifts of H-bonded N nuclei.⁶⁰ In both the redox states, six amide and two His $H^{\epsilon 2}$ N nuclei were found to exhibit paramagnetic shifts and were assigned by selective ^{15}N -labeling. Four of these are H-bonded to the $[2Fe-2S]$ cluster in the crystal structure of a homologous Rieske protein. The crystal structure also showed a fifth amide that was H-bonded to the cluster, but the homologous residue in this system did not exhibit any

hyperfine shift. The origin of the hyperfine shifts in Rieske proteins has not yet been analyzed in detail.

3.2.2 $[3\text{Fe}-4\text{S}]$ Clusters

The $[3\text{Fe}-4\text{S}]$ clusters that have been studied by NMR are found in two types of proteins: 3Fe Fds and 7Fe Fds. The 3Fe Fds are formed from Fds that contain one $[4\text{Fe}-4\text{S}]$ cluster in which one Fe is labile and is readily removed to yield a stable $[3\text{Fe}-4\text{S}]$ cluster. The 7Fe Fds contain one $[3\text{Fe}-4\text{S}]^+$ cluster and one $[4\text{Fe}-4\text{S}]^{2+}$ cluster, in which only the former can be readily reduced. The hyperfine-shifted ^1H resonances in $[3\text{Fe}-4\text{S}]^+$ clusters have substantially narrower linewidths than in $[2\text{Fe}-2\text{S}]^{2+/+}$ clusters. Hyperfine-shifted signals from $[3\text{Fe}-4\text{S}]^+$ clusters have been extensively assigned by 1D NOEs, 2D NOESY, 2D magnitude COSY, and 2D TOCSY. In all cases, the Cys H^β resonances are found in the 35 to -1 ppm range; some shift to higher frequency with increasing temperature and some to lower frequency. A representative example is *D. gigas* 3Fe Fd (Figure 4(c), Table 5).⁶¹

The chemical shifts and temperature dependencies of the hyperfine-shifted resonances are readily understood using the vector coupling model outlined above. The pattern of hyperfine-shifted resonances depends upon the relative values of the three exchange coupling parameters, J_{12} , J_{13} , and J_{23} .

From Mössbauer⁶² and temperature-dependent EPR,^{63,64} all J -values are close in magnitude but not equal. From magnetic susceptibility, J is large and negative ($|J| > 100\text{ cm}^{-1}$).⁶⁵ S_2 and S_3 are coupled to yield spin S_{23} , which ranges from 0 to 10, and S_{23} is coupled with S_1 to yield states of the form $|S_{23}, S\rangle$.⁶² One can consider three cases.^{66–70} (1) If $|J_{12}| = |J_{13}| < |J_{23}|$, then $|2, 1/2\rangle$ is the g.s., and one expects one pair of Cys H^β protons to exhibit large high-frequency shifts that decrease in frequency with increasing temperature since they are coupled to the larger spin ($S_1 = 5/2$), and the other two pairs of Cys H^β protons exhibit smaller high-frequency shifts that increase in frequency with increasing temperature (Figure 5(c), solid lines). (2) If $|J_{12}| = |J_{13}| > |J_{23}|$, then $|3, 1/2\rangle$ is the g.s., and two pairs of Cys H^β protons are expected to exhibit large high-frequency shifts that decrease in frequency with increasing temperature, since they are coupled to the larger spin ($S_{23} = 3$), and the third pair of Cys H^β protons to exhibit low-frequency shifts that increase in frequency with increasing temperature (Figure 5(c), dashed lines). (3) In the intermediate case, $|J_{12}| > |J_{13}| > |J_{23}|$, the g.s. is a mixture of $|2, 1/2\rangle$ and $|3, 1/2\rangle$, and one pair of Cys H^β protons will have high-frequency shifts that decrease with temperature, one will have minor hyperfine shifts that increase in frequency with temperature, and the third will be slightly shifted to higher frequency and weakly temperature-dependent, with the direction dependent on the exact strength of the coupling.^{66–70} Indeed, this range of behavior has been observed. The 3Fe Fds of

D. gigas^{61,67} and *T. litoralis*^{66,71} and the 7Fe Fds from *D. ambivalens*,⁶⁸ *Sulfolobus* sp. Strain 7,⁷² and *S. acidocaldarius*⁷³ are examples of the first case. Most of the other 7Fe Fds exhibit behavior of the third type^{69,70,74–78} *Pyrococcus furiosus* 3Fe Fd is somewhat different in that the two Cys H^β protons that shift to lower frequency with temperature are at slightly lower frequency than in other [3Fe–4S] clusters and have a much larger chemical shift difference between them (23.6 and 11.8 ppm).^{66,79} This was originally ascribed to magnetic coupling of the first type, but with the $S_1 = 5/2$ Fe ligated to Cys11 (equivalent to Cys8 in *D. gigas*) rather than Cys56 (equivalent to Cys50) as is found in other 3Fe Fds;⁷⁹ however, this interpretation has recently been challenged.^{70,73} In *Desulfotribrio africanus* 7Fe Fd, four resonances were found at high frequency that moved to lower frequency with increasing temperature. This would appear to be an example of the case where $|J_{12}| \approx |J_{13}| > |J_{23}|$; however, detailed assignments were not reported, and no signals were found at frequencies below the diamagnetic region as expected from the above model. Thus, in the [3Fe–4S]⁺ clusters, the vector coupling model has provided a firm basis for beginning to understand how differences among proteins modulate electronic structure.

For many years, there were essentially no reports on the hyperfine-shifted resonances in [3Fe–4S]⁰ clusters, despite an attempt to selectively ²H-label the Cys residues⁸⁰ and exploit the slower relaxation rate expected for ²H, as had been done for CpRd.¹⁰ [3Fe–4S]⁰ clusters are a case where double exchange must be considered, and it was revealed by Mössbauer that the coupling could be viewed as mixed-valent iron pair in which double exchange exceeds the effects of isotropic exchange, vibronic coupling, and static asymmetry to yield a valence-delocalized (i.e., 2Fe^{2.5+}) $S_{23} = 9/2$ state that is in turn coupled to the remaining Fe³⁺.⁸¹ In the simplest model (all J -values are equal), the Hamiltonian describing this is:

$$\mathcal{H} = -2J \sum_{i < j=1-3} \mathbf{S}_i \cdot \mathbf{S}_j \pm B \left(S_{23} + \frac{1}{2} \right) \quad (27)$$

yielding energies for the total spin states of

$$E(S) = -JS(S+1) \pm B \left(S_{23} + \frac{1}{2} \right) \quad (28)$$

From Mössbauer, the g.s. is $|9/2, 2\rangle$ which indicates that $B > 4|J|$.⁸¹ It is likely that the location of the valence-delocalized Fe^{2.5+} pair can exchange among the three irons, and such an exchange, with a rate constant of $\sim 10^5$ – 10^6 s^{−1}, was invoked as the reason the hyperfine-shift Cys resonances were not observed.⁸² Indeed, a new signal appears in the Mössbauer spectrum at higher temperatures (150 K) that indicates that all Fe sites are equivalent as a result of complete delocalization of the extra electron.⁸¹ Reduction of the [3Fe–4S]⁺ cluster at neutral pH is believed to involve protonation of the μ -sulfido bridges. Thus, chemical exchange resulting from dynamic protonation/deprotonation of the sulfides could provide the mechanism for signal broadening. Consistent with this view is the observation of very broad hyperfine-shifted NMR signals at high pH, where the protonation/deprotonation mechanism should be minimal. These signals, shifted both to higher and lower frequencies by 100–300 ppm have been preliminarily assigned to Cys H^β protons (Table 5).⁸²

3.2.3 [4Fe–4S] Clusters

[4Fe–4S] clusters have been extensively studied by NMR, much more so than all of the other classes of FeS proteins, in part because their relatively narrow hyperfine-shifted signals greatly aid in sequence-specific assignment. As listed in Table 3, they can exist in three different redox states. The [4Fe–4S]³⁺ state is found in the oxidized HiPIPs. In most of these, the protons of the ligating Cys residues have been extensively assigned by 1D NOEs, 2D NOESY, 2D magnitude COSY, 2D TOCSY, 1D saturation-transfer, and 2D EXSY. Representative ¹H NMR data from *E. halophila* HiPIP I is given in Figure 4(d) and Table 6; the latter also lists ¹³C and ¹⁵N data obtained from 2D experiments.^{38,83,84}

In the oxidized HiPIPs, the Cys H^β resonances are found throughout the 150 to −70 ppm range and vary significantly among different HiPIPs, despite their close structural homology. In all cases, however, four Cys H^β resonances shift to lower frequency with increasing temperature, and four to higher frequency. To understand this behavior it is necessary to first consider the case of *E. halophila* HiPIP II. This is the only HiPIP that exhibits four Cys H^β resonances at high field (95–45 ppm) that shift to lower frequency with increasing temperature and four at low field (−10 to −25 ppm) with the opposite temperature-dependence.^{85–87} From Mössbauer, the oxidized HiPIPs consist of a Fe³⁺ pair and a valence-delocalized Fe^{2.5+} pair that are coupled to yield a net $S = 1/2$ g.s.,^{88–90} as also shown by EPR.^{54,90,91} Noodleman explained this behavior based upon the following Hamiltonian:

$$\mathcal{H} = \sum_{i < j=1-4} -2J_{ij} \mathbf{S}_i \cdot \mathbf{S}_j \pm B_{34} \left(S_{34} + \frac{1}{2} \right) \quad (29)$$

where S_1 and S_2 are the spins of the Fe³⁺ pair and S_3 and S_4 are the spins of the Fe^{2.5+} pair ($S_1 = S_2 = 5/2$ and $S_3, S_4 = 5/2, 2$).^{34,92,93} Since J_{12} is the Heisenberg exchange coupling parameter for the Fe³⁺ pair, it is assumed to be the largest. B_{34} is the double exchange term for the valence-delocalized Fe^{2.5+} pair. This then yields the following for the energies of the total spin states:

$$E(S) = -JS(S+1) - \Delta J_{12} S_{12}(S_{12}+1) \pm B_{34} \left(S_{34} + \frac{1}{2} \right) \quad (30)$$

where $J = J_{13} = J_{14} = J_{23} = J_{24} = J_{34}$ and $\Delta J_{12} = J_{12} - J$. There are multiple states with total spin $S = 1/2$. Based upon single-crystal X-band ENDOR data on a [4Fe–4S]³⁺ model complex with very similar Mössbauer and EPR spectral properties, the correct g.s. is $|7/2, 3, 1/2\rangle$ (nomenclature is $|S_{34}, S_{12}, S\rangle$).⁹⁴ With $J_{12} > J$, this requires $6 < B_{34}/\Delta J_{12} < 8$.⁹⁵ With the same vector coupling model (see below), $J = -130$ cm^{−1}, $J_{12} = -162$ cm^{−1}, and $B_{34} = 250$ cm^{−1} yields qualitatively correct agreement with the behavior of the Cys H^β resonances of *E. halophila* HiPIP II (Figure 5(d)).^{32,86,96,97} In a slightly more sophisticated model in which $J_{34} \neq J$, B_{34} and J_{34} are covariant, and hence it currently is not possible to determine any of the parameters independently. This has led to considerable debate as to the exact values to use for the Heisenberg and double exchange parameters.^{95,98} Regardless, the picture remains the same: signals of the Cys ligated to the Fe^{2.5+} pair will be shifted to higher frequency and those ligated

^a298 K.^bThese values were not reported in tabulated form, but were read off the published spectrum⁸⁴ and are therefore approximate.

to the Fe³⁺ pair will be shifted to lower frequency. ¹H hyperfine data of the other HiPIPs, in which only two resonances are at lower frequency than the diamagnetic region, have been explained by invoking a spin equilibrium mechanism, in which the location of the delocalized Fe^{2.5+} pair alternates between two different sets of Fe atoms with the exchange rapid on the NMR timescale.⁹⁹ Based upon the *E. halophila* HiPIP I sequence, Cys 33, 36, 50 and 66 are designated I, II, III, and IV, respectively. In *E. halophila* HiPIP II, Cys I and IV ligated to the Fe³⁺ pair and Cys II and III are ligated to the delocalized Fe^{2.5+} pair. All other HiPIPs exist in equilibrium between this arrangement and a second one, in which Cys I

and II are ligated to the Fe³⁺ pair and Cys III and IV are ligated to the delocalized Fe^{2.5+} pair. Thus, in *E. halophila* HiPIP I, Cys II experiences ~20% Fe³⁺ character, and Cys IV ~20% Fe^{2.5+} character. The degree in which the delocalized Fe^{2.5+} pair is found ligated to Cys III and IV increases in the order *E. halophila* iso I, *R. globiformis*, *E. vacuolata* iso I, *E. vacuolata* iso II, *C. vinosum*, *R. gelatinosus*, and *R. fermentans*. In the last two HiPIPs, Cys II experiences ~70% Fe³⁺ character, and Cys IV ~70% Fe^{2.5+} character.^{100,101} This spin equilibrium model also explains the noticeable deviation in linearity in the temperature dependencies of the Cys H^β protons in *E. vacuolata* HiPIP II, behavior that is not readily accounted for

by other models.⁹⁹ In addition, the EPR spectra of oxidized HiPIPs exhibit a mixture of $S = 1/2$ species in all cases except *E. halophila* iso II. These results have been described in terms of the same model as given above, where now the two species are either frozen out or are exchanging on a timescale slower than the EPR experiment.⁹⁹ The vector coupling picture and the spin equilibrium model provide a remarkably reliable basis for understanding a range of features seen among the oxidized HiPIPs. The exception again is the failure of the simple vector coupling picture to explain the hyperfine shifts of ^{13}C nuclei, in particular the Cys C^α resonances.³⁸

The $[\text{4Fe-4S}]^{2+}$ state is found among all $[\text{4Fe-4S}]$ proteins: HiPIPs, the 4Fe, 7Fe, and 8Fe ferredoxins (which in the oxidized state contain 2 $[\text{4Fe-4S}]^{2+}$ clusters), and two other systems that have been examined by NMR, the nitrogenase Fe-protein and the PsaC subunit of photosystem I. The Cys protons are found in the 22–0 ppm range and always increase in frequency with increasing temperature. In a number of systems, they have been sequence-specifically assigned by the usual assortment of 1D and 2D NMR experiments. Representative data from cluster I of the *C. acidi-urici* 8Fe Fd is given in Figure 5(e) and Table 6.¹⁰² The $[\text{4Fe-4S}]^{2+}$ cluster consists of two nearly identical $\text{Fe}^{2.5+}$ pairs that are antiferromagnetically coupled to yield a net $S = 0$ g.s., as shown by Mössbauer spectroscopy on reduced HiPIPs,^{88,89} oxidized 8Fe and 4Fe Fds,^{103–105} and oxidized nitrogenase Fe-protein.¹⁰⁶ Thus, as in the case of the $[\text{2Fe-2S}]^{2+}$ clusters, the hyperfine shifts arise solely from thermal population of paramagnetic excited states. This behavior can be readily fit by using a Hamiltonian of the sort in equation (29) and adding another $B_{12}(S_{12} + 1/2)$ term to account for double exchange in the second valence-delocalized $\text{Fe}^{2.5+}$ pair.^{34,93,96,97,107} In the simplest possible model all J -values are equal, yielding the following for the energy of the total spin states:

$$E(S) = -JS(S+1) \pm B_{12}\left(S_{12} + \frac{1}{2}\right) \pm B_{34}\left(S_{34} + \frac{1}{2}\right) \quad (31)$$

This readily accounts for the observed hyperfine shifts of the Cys H^β resonances (Figure 5(a), dashed lines).^{96,97,107}

The $[\text{4Fe-4S}]^+$ state occurs in the reduced 4Fe and 8Fe ferredoxins, nitrogenase Fe-protein, and PsaC subunit of photosystem I. The Cys protons are found in the 65 to –5 ppm range and exhibit a mixture of temperature-dependent behavior: some shift to higher frequency and some to lower frequency with increasing temperature. Representative data from cluster I of the *C. acidi-urici* 8Fe Fd is given in Figure 5(f) and Table 6.¹⁰² In this system and a number of others, the Cys protons have been sequence-specifically assigned by 1D and 2D NMR experiments and in particular, with the use of 2D EXSY and existing assignments of the oxidized form.^{102,108} In reduced *C. acidi-urici* 8Fe Fds and in most other cases, the H^β resonances of two Cys residues shift to higher frequency with increasing temperature, and the other two to lower frequency, and all occur in roughly the same chemical shift range.^{102,108} Mössbauer spectroscopy indicates that the $[\text{4Fe-4S}]^+$ cluster consists of a Fe^{2+} pair and a valence-delocalized $\text{Fe}^{2.5+}$ pair.^{103–106,109} In general, the g.s. is $S = 1/2$, although there are notable exceptions, discussed below.⁴⁷ The exchange coupling in the $[\text{4Fe-4S}]^+$ cluster is significantly more complex than in other FeS clusters. The decrease in the average valence of the four Fe atoms leads

to a decrease in the magnitude of J , which in turns means that B has a proportionally greater influence and that the total spin states are closer in energy.^{34,93,110–113} Nonetheless, some insight may be gained by the same simple model as used in equations (29) and (30), where now S_1 and S_2 are the spins of the Fe^{2+} pair and S_3 and S_4 are the spins of the $\text{Fe}^{2.5+}$ pair ($S_1 = S_2 = 2$ and $S_3, S_4 = 5/2, 2$). With reasonable estimates for J and B_{34} one obtains the qualitatively correct behavior of the Cys H^β resonances: those ligated to the $\text{Fe}^{2.5+}$ pair shift to lower frequency with increasing temperature and those ligated to the Fe^{2+} pair shift to higher frequency, and all of them will be higher frequency than the diamagnetic region (Figure 5(f)).

P. furiosus 4Fe Fd is an unusual case. First, one of the ligands to the cluster is an Asp instead of a Cys. Second, the g.s. is a physical mixture of $S = 3/2$ and $S = 1/2$ species based upon EPR.¹¹⁴ The temperature dependencies of the hyperfine-shifted resonances in the reduced state are complex and very unusual; for example, the H^β protons of Cys17 exhibit *opposite* temperature dependence.^{115–117} In contrast, the D14C mutant exhibits hyperfine behavior extremely similar to those of other 4Fe and 8Fe Fds; specifically, the H^β protons of Cys11 and 17 shift to lower frequency with increasing temperature and are assigned to the $\text{Fe}^{2.5+}$ pair, and Cys14 and 56 shift to higher frequency and are assigned to the Fe^{2+} pair.¹¹⁶ Similarly, from EPR, the g.s. is purely $S = 1/2$.¹¹⁸ The unusual hyperfine temperature-dependent behavior observed in the wild-type was explained by invoking a spin-equilibrium model similar to that for the oxidized HiPIPs. In one arrangement, Cys 14 and 56 ligate the $\text{Fe}^{2.5+}$ pair and Cys 11 and 17 the Fe^{2+} pair, and in the other, Cys 14 and 17 ligate the $\text{Fe}^{2.5+}$ pair and Cys 11 and 56 the Fe^{2+} pair, indicating that Asp stabilizes the mixed-valence $\text{Fe}^{2.5+}$ pair.¹¹⁶ Notably, the hyperfine shifts and relaxation rates of the ligand protons in the wild-type protein are not significantly different from other $[\text{4Fe-4S}]^+$ clusters, leading to the conclusion that the presence of $S = 3/2$ species in the EPR spectrum is an artifact of freezing and that in solution the g.s. is purely $S = 1/2$.¹¹⁵ A similar picture exists for the nitrogenase Fe-protein, which also exists as a mixture of $S = 3/2$ and $S = 1/2$ species based upon EPR and Mössbauer.^{106,109} Addition of urea increases the fraction of the $S = 3/2$, and addition of ethylene glycol decreases it.¹⁰⁶ Again, the NMR spectra are not significantly different from those of other $[\text{4Fe-4S}]^+$ clusters.^{119,120} Indeed, the addition of urea or ethylene glycol had little effect, leading to the conclusion that in solution the g.s. is purely $S = 1/2$.

4 CONCLUDING REMARKS

The last decade has seen a dramatic increase in our understanding of electron–nuclear interactions. We have progressed from merely noting the different sorts of the hyperfine-shifted resonances in paramagnetic proteins to being able to accurately calculate them. Relaxation rates are now often used as distance constraints in solution structure determination. The use of residual dipolar couplings holds similar promise. The vector coupling model has been enormously successful in explaining the ^1H hyperfine data in FeS clusters and has contributed greatly to our understanding of the exchange coupling in these complex systems. Further refinement of this model to help better explain ^{13}C and ^{15}N hyperfine data is needed and may lead

to further insights. With these tools in hand, NMR will be capable of answering detailed questions regarding how H-bonds and other aspects of the protein matrix tune the properties of metal active sites and thus their function. Thus, while paramagnetic NMR already is acknowledged as one of the most powerful spectroscopic methods available for investigating the biophysics of metalloproteins, it is now poised to assume similar importance for studies of metalloprotein biochemistry.

Biographical Sketches

Timothy E. Machonkin, b 1971, B.S. Chemistry, 1993, Ph.D., 2000, Stanford University. Dr. Machonkin has been working in the area of bioinorganic chemistry since an undergraduate. In the laboratory of Prof. Edward Solomon at Stanford, he was involved in spectroscopic studies of metalloproteins and model systems, and in particular, EPR and magnetic susceptibility of Cu-containing systems. Since joining the laboratory of Prof. Markley, he has worked on NMR of FeS systems and the development of new methods to study paramagnetic systems with slow electronic relaxation rates by NMR.

John L. Markley, b 1941, B.A. Chemistry, 1963, Ph.D., 1969, Harvard University. Dr. Markley is Steenbock Professor of Biomolecular Structure in the Department of Biochemistry at the University of Wisconsin-Madison. He is Head of the National Magnetic Resonance Facility at Madison and the BioMagResBank, the international repository for biomolecular NMR data. Recently, he became Director of the Center for Eukaryotic Structural Genomics at the University of Wisconsin-Madison.

Electron–Nuclear Multiple Resonance Spectroscopy

1 INTRODUCTION

The term ‘pulsed electron–nuclear multiple resonance’ (PE NMR) spectroscopy refers to a broad range of experimental methods in which pulsed NMR techniques are combined with pulsed electron paramagnetic resonance (EPR) techniques. This combination provides the capability to measure the spectra and spin dynamics of nuclei which are magnetically coupled to unpaired electrons by the hyperfine interaction. Related experimental techniques for measuring the interactions of nuclei coupled to unpaired electrons are paramagnetically shifted NMR, dynamic nuclear polarization (DNP), electron spin resonance (ESR), the pulsed ESR technique of electron spin echo envelope modulation (ESEEM), and continuous wave (CW) electron–nuclear double resonance (ENDOR). These techniques are complementary rather than competing methods for measuring different aspects of the magnetic interactions of the coupled electron–nucleus spin system. Each technique offers certain advantages as well as certain limitations. The most appropriate experimental approach for a given problem also depends on the type of information desired.

The PE NMR techniques discussed in this article are best suited for measuring the magnetic interactions of nuclei in the local coordination structure of a paramagnetic electron. A distinguishing characteristic of nuclei which are detected in PE NMR experiments is that the NMR transition frequencies are shifted by very large values when compared with NMR spectra of diamagnetic samples. These large shifts arise from the large local magnetic fields originating from the unpaired electron spins. Consequently, the resonance frequency is described by the hyperfine coupling and is measured in units of kilohertz or megahertz as opposed to a resonance frequency shift of parts per million referenced to the nuclear Larmor frequency of a standard.

Nuclei which experience large local magnetic fields originating from unpaired electrons are encountered in a wide spectrum of research areas, including chemistry, materials science, polymer science, environmental science, and the biological sciences. Specific examples include: organic and inorganic radical molecules;^{1–3} fossil fuels;^{4,5} organic conductors, semiconductors and electroactive polymers; organometallic transition metal complexes;^{6,7} dopants and other localized states

in semiconductors;⁸ surfaces such as on oxides and semiconductors; at the internal interfaces of semiconductors, superlattice structures, polymers, and composite materials; catalysis; transition metal ions in zeolites; and at the active sites for electron transfer or substrate binding in metalloproteins and metalloenzymes.⁹

If the unpaired electron spins can be treated as independent (or only weakly coupled) dipoles, their magnetic susceptibility is described by paramagnetism. Nuclei which sustain a hyperfine coupling with such electrons are therefore also referred to as paramagnetically coupled nuclei. Under certain conditions the NMR spectrum of paramagnetically coupled nuclei can be observed directly in the NMR spectrum as a paramagnetic shift. This is usually identified by the magnitude of the frequency shift and its temperature dependence. The local magnetic field originating from the unpaired electron spin shifts the NMR frequency and broadens the linewidth for those nuclei which sustain a hyperfine interaction. Both the magnitude of the frequency shift and the linewidth depend on the magnitude of the hyperfine coupling and on the details of the spin dynamics, specifically on the spin relaxation rates of the electron and nuclei. Well-resolved NMR lines can be observed if the electron spin–lattice relaxation time T_{1e} , or electron spin correlation time τ_e , which describes the time dependence of the local magnetic field, is short enough to assure that the orientation dependence of the local field is time averaged to its isotropic value. The paramagnetic shift is then determined by the isotropic hyperfine coupling arising from the unpaired spin density on the nucleus. Several texts have been written which describe the theory and applications of NMR to paramagnetic molecules including proteins and enzymes with paramagnetic transition metal ions.^{10–12}

The short electron spin relaxation time required to observe paramagnetically shifted nuclei directly in NMR spectra also typically result in very broad ESR linewidths. In fact, as a rough guide, paramagnetically shifted NMR transitions are usually only observed in cases where the ESR spectrum is too broad to be observed. However, very broad ESR linewidths can also originate from inhomogeneous line broadening, even if the electron spin relaxation times are very long. In either case, if an ESR spectrum is observed, several experimental approaches are potentially applicable for the measurement of the magnetic interactions of the hyperfine coupled nuclei in these cases. These include DNP, ESR, ESEEM, ENDOR, and the extension of the latter to PE NMR.

In DNP spectroscopy the hyperfine coupling is used as a mechanism to enhance the nuclear polarization. The details of the mechanism for this enhancement and the magnitude of the enhancement depend on the details of the hyperfine interaction, particularly on the time dependence of the hyperfine coupling, and on the details of the ESR spectrum, such as the ESR linewidth and relaxation time. The theory and applications of DNP spectroscopy have been discussed in several texts and review articles.^{13–18} (See *Dynamic Nuclear Polarization and High-Resolution NMR of Solids*.) Here we discuss only those aspects of DNP spectroscopy that are relevant for comparison and contrast with the related techniques mentioned above.

In DNP spectroscopy the NMR signal is detected directly. The ESR transition is used only as a source for achieving enhanced nuclear polarization. Theoretically a maximum enhancement of the NMR signal of the order of ω_e/ω_n can be achieved, but in practice significantly lower values are

usually observed. Direct detection of the NMR signal has the advantage that the high resolution of NMR spectroscopy is maintained. At the same time, this excludes from detection those nuclei which have large hyperfine couplings. This is a result of the combination of low sensitivity and the large shift in transition frequencies. DNP spectroscopy has been applied most successfully in cases where the ESR spectrum consists of a narrow line which is easily saturated. Examples include studies of fossil fuels¹⁹ and polymer interfaces.^{20–22}

Paramagnetically coupled nuclei may be observed directly as hyperfine splittings in the ESR spectrum. Such splittings are often observed in ESR spectra of organic radical molecules in liquids (see *Electron–Nuclear Hyperfine Interactions*). However, if the spin dynamics are not in the fast motion limit, hyperfine splittings are generally not resolved because of inhomogeneous line broadening.

Two different general approaches are available for measuring the magnetic couplings of nuclei which are not resolved in the ESR spectra. One approach is ESEEM.^{23–26} In this technique both the allowed and the semiforbidden ESR transitions are coherently excited using two or more short, intense microwave pulses. The nuclear hyperfine and quadrupole interactions (in the case of nuclei with spin multiplicity $I \geq 1$) are observed as a periodic modulation of the envelope of the primary spin echo or stimulated echo intensity. Fourier transformation of this modulation pattern yields a spectrum of frequencies corresponding to the hyperfine (and quadrupolar for $I \geq 1$) frequencies.

One of the advantages of the ESEEM experiment is its high sensitivity, which is roughly comparable with that obtained in an ESR experiment. Furthermore, by selecting the appropriate microwave excitation frequency and applied magnetic field conditions, it is possible to measure the pure nuclear quadrupolar resonance frequencies for nuclei with $I \geq 1$.^{27,28} This is possible despite the fact that the experiment is performed at finite magnetic field and the only spin transitions that are excited are the ESR transitions. One limitation of this type of experiment is that nuclear modulation can only be observed if the hyperfine interaction has finite anisotropic coupling components. The second criterion for modulation to be observed is that the microwave pulses must be able to excite both allowed and semiforbidden ESR transitions. This places constraints on the nature of the hyperfine interaction which will yield observable modulation. The theory, techniques, and applications of ESEEM spectroscopy have been reviewed in several texts and review articles.^{23–27,29}

The second approach for measuring the magnetic couplings of nuclei which are not resolved in the ESR spectra is directly to excite both the NMR and ESR transitions with rf and microwave excitation. The first double resonance experiment of this type, known as an ‘electron–nuclear double resonance’, or simply ENDOR, experiment was reported by Feher in 1956.³⁰ The continuous wave (CW) ENDOR experiment is performed by applying a strong microwave field which is selected to irradiate continuously an EPR transition while simultaneously applying a strong rf field. The rf field is swept through the range of frequencies that encompass the NMR spectrum while continuously observing the intensity of the EPR transition. The intensity of the latter changes whenever the rf frequency matches an NMR transition frequency. The intensity of the EPR transition plotted as a function of the rf frequency generates the ENDOR spectrum. Thus, the

ENDOR spectrum is a spectrum of the NMR transitions detected indirectly via the EPR transition. This is in contrast to the ESEEM experiment where the nuclear spin flip is a consequence of exciting a semiforbidden ESR transition. As a result, anisotropic hyperfine interactions are not necessary to observe hyperfine frequencies in the ENDOR experiment.

The ENDOR technique and applications have been documented in several texts and review articles.^{1,8,9,31–36} In the case of one electron coupled to a spin- $\frac{1}{2}$ nucleus, and considering for simplicity that the hyperfine interaction is isotropic, the ENDOR spectrum comprises two transitions corresponding to one NMR transition for each of the two electron spin states. There exists a one-to-one correspondence between the number of coupled inequivalent nuclei and the number of ENDOR transitions observed. This can be contrasted to the number of transitions observed in the EPR spectrum where the number of transitions observed is a multiplicative function of the number of inequivalent nuclei coupled to the unpaired electron spin. The reduced number of transitions results in spectral simplification and, consequently, in enhanced spectral resolution.

While the success of the CW ENDOR experiment has been well documented, certain inherent problems in the technique have also limited its applicability. One well-documented limitation of the CW ENDOR experiment is the constraints on the relationship between NMR and ESR relaxation rates that must be satisfied in order to observe an ENDOR signal.^{31,32,37–41} These constraints are changed (although not removed) with pulsed excitation techniques. This was recognized by W. B. Mims who reported the first pulsed ENDOR experiment in 1965, roughly a decade after Feher’s initial report of the CW ENDOR experiment. Since then the advantages and applications of employing pulsed excitation techniques for both the ESR and NMR transitions have been demonstrated in publications from several laboratories.^{37,38,41–46}

A second significant advantage of employing pulsed excitation techniques for both the ESR and NMR transitions is the potential for extending the type of experiments which can be performed. This is in many respects analogous to the extension of the experimental capabilities which become possible using pulsed excitation techniques in NMR spectroscopy. There are, however, distinct differences that must be kept in mind when using the analogy to pulsed NMR. These will be discussed in more detail in the next section. Furthermore, since multiple irradiation frequencies may be used to excite both the NMR and EPR transitions, the modern combined pulsed NMR and pulsed EPR experiments will be referred to as ‘pulsed electron NMR’ (PE NMR) spectroscopy. In this article, we describe the basic principles of these techniques, their implementation, including the pulse schemes and specific examples of experimental techniques, and illustrate the type of information that can be derived with examples in selected applications.

2 BASIC PRINCIPLES

In this section the magnetic interactions that determine the frequencies and amplitudes in pulsed ENDOR spectra are briefly reviewed. More comprehensive treatments can be found in several texts.^{2,6,31,32,47,48} The analysis of the pulsed ENDOR spectrum provides the starting point for understanding the extensions of the basic pulsed ENDOR technique. After

the properties of the pulsed ENDOR spectrum have been presented, the general approach for the PE NMR techniques will be introduced. This is followed by specific experimental techniques with examples of applications.

2.1 Nuclear Spin Interactions and the Spectrum

2.1.1 Transition Frequencies

For spin- $\frac{1}{2}$ nuclei, the NMR spectrum of the paramagnetically coupled nuclei is dominated by the local magnetic field generated by the unpaired electron spin and by the applied magnetic field. The magnitude and orientation of this local field depends on whether the electron spin is aligned along or opposed to the direction of the external magnetic field. The effect of the combined local field and applied field on the nuclear spin is described by the nuclear spin Hamiltonian (expressed in units of frequency)

$$\hat{\mathcal{H}}_n = \sum_{i=1}^3 (\hat{\mathbf{S}}' \cdot \mathbf{A} - g_n \beta_n B_0 b_i) \hat{I}_i \quad (1)$$

where the subscript $i = 1, 2, 3$ on $\hat{I}_i$ refers to the x, y, z components of the nuclear spin operator $\hat{\mathbf{I}}$. The prime on the electron spin operator $\hat{\mathbf{S}}'$ indicates that a coordinate system is selected in which the $\mathbf{g}$ tensor is diagonal. The b_i are the unit vectors of the applied magnetic field expressed in spherical polar coordinates:

$$(b_1, b_2, b_3) = (\cos \phi \sin \theta, \sin \phi \sin \theta, \cos \phi) \quad (2)$$

In most pulsed EPR experiments, particularly on transition metal ions, the microwave pulses excite only a small region of the spectrum centered about the magnetic field for resonance. This magnetic field position selects a subset of molecular orientations defined by the resonance condition, $h\nu = g\beta B_0$, where the orientation dependence of the electronic g factor is expressed by

$$g(\theta, \phi) = \left[\sum_{i=1}^3 (g_i b_i)^2 \right]^{1/2} \quad (3)$$

The number of molecular orientations which contribute to the ENDOR spectrum is minimum for values of (θ, ϕ) that correspond to the principal axes of the $\mathbf{g}$ tensor. This phenomenon is referred to as g -factor orientation selectivity.⁴⁹ Since a lower number of molecular orientations contribute, higher spectral resolution can be observed in ENDOR spectra recorded at magnetic field values corresponding to those values of (θ, ϕ) which correspond to these principal axes.

The local field is described by the term $\hat{\mathbf{S}}' \cdot \mathbf{A}$, where $\mathbf{A}$ is the hyperfine interaction tensor. The magnitude of the local field depends on the distance between the electron and the nucleus and on the nature of the chemical bonding that pertains to the electron and nucleus, i.e. on the electronic state in which the electron resides. The distance separating the electron and nucleus determines a classical dipolar interaction. Since the gyromagnetic ratio of the electron is very large, this

local magnetic field can be very large. The classical dipolar field will only provide a valid description of the distance between the electron and nucleus if the electron can be treated as a point dipole. Contributions to the hyperfine anisotropy also depend on the nature of the electronic wavefunction. The latter also determines whether the nucleus has a finite unpaired electron spin density at the nucleus. A finite unpaired spin density at the nucleus can only occur if the molecular orbital that describes the unpaired electron has some atomic s-orbital contribution in the wavefunction. The nonclassical contribution to the hyperfine anisotropy is sometimes referred to as 'pseudodipolar coupling'.

The orientation dependence of the local field can be expressed by an orientation-dependent hyperfine coupling $A(\theta, \phi)$. The NMR transition frequencies are then given by

$$\nu_{\pm} = \nu_n \pm \frac{1}{2} |A(\theta, \phi)| \quad (4a)$$

$$\nu_{\pm} = \frac{1}{2} |A(\theta, \phi)| \pm \nu_n \quad (4b)$$

where the first expression applies if $2\nu_n > |A|$ and the second expression applies if $2\nu_n < |A|$, while in both cases it is assumed that $I = \frac{1}{2}$.

The two limiting expressions [equations (4a) and (4b)] for the NMR frequencies are a recognition of the fact that the local magnetic field described by the hyperfine interaction can be comparable to or larger than the applied magnetic field. This is especially the case at the low applied field strengths, typically 0.35 T, at which many ENDOR and PE NMR experiments are performed. If the local field is greater than the applied field, then the local field is the dominant term that defines the nuclear quantization axis and the applied field is a perturbation. In either case, equations (4a) and (4b) indicate that for a nucleus with $I = \frac{1}{2}$, two NMR transitions will be observed in the ENDOR spectrum, with one transition originating from each of the two electron spin manifolds defined by the eigenvalue, $m_{S'}$, of $\hat{\mathbf{S}}'$. These NMR transitions will either be centered on the nuclear Larmor frequency if $2\nu_n > |A|$ or on one-half of the hyperfine coupling if $2\nu_n < |A|$.

In the case of organic radicals, the anisotropy of the g factor can be ignored in the first order analysis of the paramagnetically shifted NMR transitions. The NMR transition frequencies $\nu_{\pm}$ are then given by⁵⁰

$$\begin{aligned} \nu_{\pm} = & [(S_z A_{xx} - \nu_n)^2 \sin^2 \theta \cos^2 \phi \\ & + (S_z A_{yy} - \nu_n)^2 \sin^2 \theta \sin^2 \phi \\ & + (S_z A_{zz} - \nu_n)^2 \cos^2 \theta]^{1/2} \end{aligned} \quad (5)$$

where θ and ϕ are the spherical polar angles relating the applied static field $\mathbf{H}_0$ to the principal axis of the hyperfine tensor (A_{xx}, A_{yy}, A_{zz}). Equation (5) assumes that the high-field approximation is valid where the electron and nuclear spin operators $\hat{\mathbf{S}}$ and $\hat{\mathbf{I}}$ are completely decoupled from the molecular framework and quantized along the applied magnetic field direction. An energy level structure corresponding to an arbitrary selected set of (θ, ϕ) values is shown in Figure 1.

In general, the g factor for the electron will not be isotropic as assumed in the expressions described by equations (4a), (4b) and (5). Anisotropy of the electron g factor is usually

significant in ESR spectra of transition metal ions.^{6,7} If the g factor is anisotropic, the NMR frequencies and lineshape will depend on the magnetic field position and microwave frequency selected.^{6,48,51,52} In a noncrystalline solid, a single pair of NMR transitions will only be observed if the principal axes of the $\mathbf{g}$ and $\mathbf{A}$ matrices are collinear. Otherwise a powder pattern lineshape will be observed because of the angular dependence of the $\mathbf{g}$ and $\mathbf{A}$ matrices.

The NMR frequencies described in equation (5) do not account for the second-order frequency shifts of the ENDOR lines observed for large hyperfine couplings. Since these second-order frequency shifts are proportional to $A^2/4\nu_e$, they can usually be ignored under most experimental conditions. However, even for relatively small hyperfine coupling values, these second-order effects, arising from the spin Hamiltonian terms $\hat{S}_x\hat{I}_x$ and $\hat{S}_y\hat{I}_y$ must be included to calculate correct wave functions that reproduce the rf frequency dependence of the ENDOR amplitudes. These spin coupling terms lead to an enhancement, known as the ‘hyperfine enhancement’, of the rf field seen by the nucleus. Note that the enhancement can also be negative, i.e. a decrease in the rf field at the nucleus, depending on the eigenvalue m'_S of $\hat{S}'$.

The simple four-level system with isotropic hyperfine coupling described by the spin Hamiltonian:

$$h^{-1}\hat{\mathcal{H}}_0 = \nu_e\hat{S}_z - \nu_n\hat{I}_z + a\hat{S}_z\hat{I}_z \quad (6)$$

is usually adequate for describing the basic concepts for the sublevel polarization transfer experiments as well as several other PE NMR experiments described later in this article. In the high temperature limit, i.e. $g_e\beta_e B_0/kT \ll 1$, the spin eigenvalues, $h^{-1}E_0(M_S, M_I)$, are given by:

$$h^{-1}E_0(M_S, M_I) = \nu_e M_S - \nu_n M_I + a M_S M_I \quad (7)$$

The energy levels in Figure 1 also describe these eigenstates which arise from the coupling of an $S = I = \frac{1}{2}$ system with isotropic hyperfine coupling. With this level of simplification it is possible to gain considerable insight into the spin dynamics of PE NMR experiments using the spin operator formalism⁴² frequently used in NMR spectroscopy.⁵³

Figure 1 Energy level structure corresponding to the spin Hamiltonian of a four-level system. EPR, ENDOR, and relaxation transitions are identified

In the literature on pulsed ENDOR and PE NMR spectroscopy, the hyperfine splitting of the electron spin eigenstates are referred to as ‘hyperfine sublevels’ or simply as ‘sublevels’. The EPR, NMR, and spin relaxation transitions relevant in the discussion of the ENDOR experiment are identified in Figure 1. The ENDOR transitions indicated in the figure are NMR transitions detected indirectly by the ESR transition. The electron and nuclear relaxation transition probabilities W_e and W_n correspond to effective T_{1e}^{-1} and T_{1n}^{-1} rates; these are also identified in Figure 1. In the analysis of signal amplitudes in the CW ENDOR experiment, the effective rates are the intrinsic rates enhanced by the application of the microwave or rf excitation fields.

If the nuclear spin multiplicity $I \geq 1$, the quadrupolar interaction will result in additional splittings of the hyperfine sublevels. The quadrupolar interaction is described by adding the nuclear self-coupling term, $\hat{\mathbf{I}} \cdot \mathbf{P} \cdot \hat{\mathbf{I}}$ to the spin Hamiltonians of either equation (1) or equation (6). If the principal axes of the $\mathbf{g} \cdot \mathbf{A} \cdot \mathbf{P}$ are collinear and the magnetic field $\mathbf{B}_0$ is oriented parallel to one of these principal axes, the first-order ENDOR frequencies are given by^{2,6,48}

$$\nu_{\text{ENDOR}} = \left| \frac{A_i}{2} \pm \nu_n \pm \frac{3}{2}|P_i|(2m_i + 1) \right| \quad (8)$$

where A_i and P_i denote the principal values of the $\mathbf{A}$ and $\mathbf{P}$ tensors along the i axis. The nuclear transitions in equation (8) are assumed to increase in the nuclear spin quantum number, i.e. $m_I \rightarrow m_I + 1$. It has also been assumed that $(|A| > 2\nu_n > 3|P_i|)$. The principal values of the quadrupolar tensor $\mathbf{P}$ are defined as $|P_{zz}| > |P_{yy}| > |P_{xx}|$. These principal values are related to the magnitude of the quadrupolar coupling constant χ and asymmetry parameter η by

$$\chi = 2I(2I - 1)P_{zz} \quad (9a)$$

$$\eta = \frac{P_{xx} - P_{yy}}{P_{zz}} \quad (9b)$$

According to equation (8), four ENDOR transitions are expected for a nucleus with $I = 1$. However, not all ENDOR transitions may be observed when exciting an ESR transition at a given magnetic field value, since it is possible that each m_I state may be selectively excited. For example, a two-line ENDOR spectrum will be observed if the ESR transition connects the $m_I = 1$ to $m_I = 1$ sublevels of the $m_S = +\frac{1}{2}$ and $m_S = -\frac{1}{2}$ electron spin manifolds.

2.1.2 ENDOR Amplitudes

ENDOR signal amplitudes are proportional to the change in the EPR signal intensity, ΔE , induced by an NMR transition. Since the EPR signal intensity E is proportional to the electron spin susceptibility χ_e , a relative ENDOR susceptibility can be defined by

$$\frac{\Delta\chi_e}{\chi_e} = \frac{\Delta E}{E} \quad (10)$$

The transition frequencies and amplitudes that are described by the time-independent terms in the spin Hamiltonian are independent of the method of exciting and detecting the transitions. However, the dynamic terms of the total spin Hamiltonian that describe the spin system have different effects on the amplitudes in the CW and pulsed experiment. In the CW experiment, the ENDOR signal amplitude depends on the rate at which the ESR and NMR transitions are excited by the applied microwave and rf magnetic fields compared with the rate of intrinsic relaxation pathways that will compete to restore the spin system to thermal equilibrium. Once the spin eigenstates and relaxation rates that connect the eigenstates have been defined, coupled rate equations can be used to model the ENDOR signal amplitude. In contrast, the pulsed ENDOR or ENMR experiment is performed on a timescale which is short compared with the intrinsic spin relaxation rates. The amplitudes can therefore be analyzed without resorting to coupled rate equations.

In the CW experiment, the interplay between the transition intensity induced by the applied magnetic fields and the intrinsic spin relaxation rates is further complicated by the effect of the hyperfine enhancement on the ENDOR amplitudes.^{31,32,50,54} For intense rf fields, the ENDOR amplitudes can be independent of the rf frequency. For very weak rf fields, the ENDOR amplitudes increase with the square of the rf frequency. For intermediate values, the ENDOR amplitudes can be a complex function of the transition moments and relaxation parameters, especially since both the transition moments and the relaxation rates can be orientation dependent.

In pulsed ENDOR experiments, the analysis of the hyperfine enhancement and the effects of the spin relaxation on the ENDOR amplitudes is less complex. The pulsed ENDOR experiment is usually performed on a timescale which is short compared with the electron, nuclear, and the electron–nucleus cross-relaxation rates. In this case the relaxation rates do not influence the relative ENDOR amplitudes. The loss of electron spin polarization by T_{1e} processes during the mixing period (described in Section 2.2) results in a uniform decrease in the signal amplitudes, $\Delta\chi_e/\chi_e$, across the ENDOR spectrum. The hyperfine enhancement of the NMR transition moment is then simply observed as a change in the sublevel nutation angle as a function of rf frequency. The sublevel nutation angle θ_R is given by $\theta_R = \gamma_n \epsilon B_2 t_{rf}$, where ϵ is the hyperfine enhancement factor. If the hyperfine interaction is isotropic, the hyperfine enhancement factor is given by $\epsilon = |1 + m_s a/\nu_n|$. The hyperfine enhancement can be observed directly in EPR detected sublevel transient nutation experiments.^{43,55}

As described in the next section, the pulsed ENDOR experiment can be divided into pulse periods. The ENDOR amplitude is a function of the microwave pulses in the preparation period and detection period as well as of the nutation angle of the sublevel polarization in the mixing period. The latter can be expressed by

$$EA(\nu_{rf}) = \frac{1}{2}(1 - \cos(\theta_{R\pm})) \quad (11)$$

In the limit of small nutation angles, the cosine term can be expanded in a power series:

$$EA(\nu_{rf}) \approx \frac{(\theta_{R\pm})^2}{4} = \frac{(m_s A)^2}{(2\nu_n)^2} = \frac{(m_s)^2}{(2\nu_n)^2} (\nu_{\pm} - \nu_n)^2 \quad (12)$$

Equation (12) explicitly indicates that the Fermi golden rule result for the rf frequency dependence of the transition probability is obtained in the limit of small nutation angle. If the nutation angle is adjusted to correspond to a π pulse at each ENDOR frequency, the ENDOR amplitudes should be independent of the hyperfine enhancement factor. It is straightforward, although time consuming, to measure the sublevel nutation frequency at each ENDOR frequency in the ENDOR spectrum for a quantitative analysis of the ENDOR amplitudes. Additional contributions to the ENDOR amplitudes arise from the effect of hyperfine contrast selectivity in the preparation period and from possible electron–nucleus coherence effects in the detection period.^{37,38} These effects are discussed in more detail in Section 3. Contributions originating from the hyperfine anisotropy^{6,48} and g -factor orientation selectivity^{6,48} will also affect the amplitudes in both the CW and pulsed ENDOR experiments.

2.2 Pulse Schemes

Many of the PE NMR experimental techniques can be understood by analogy to heteronuclear NMR experiments. However, in making this comparison between PE NMR and heteronuclear NMR experiments, some important differences must be recognized. These originate from the fundamental properties of the unpaired electron compared with a nucleus. The two most significant differences are the γ values of the electron and nucleus and the differences between the nature of the wave functions that describe the electron and the nucleus.

The larger γ for the electron compared with any nucleus has two important consequences. The first is the practical consequence for the type of instrumentation required for PE NMR experiments compared with heteronuclear NMR experiments. The heteronuclear NMR experiment requires a transmitter, probe, and receiver capable of handling two (or more) different rf frequencies. In contrast, for the double resonance experiment between the electron and nucleus, the hardware must be capable of handling both rf and microwave frequency components.

A second consequence of the larger γ of the electron is that the local magnetic field generated by the electron is much larger than is generated by any nucleus. This has several consequences on the properties of the spectra observed for nuclei that are coupled to this local field and also has implications on the types of experiments which can be performed. In most cases, PE NMR experiments must be analyzed within the so-called ‘soft pulse limit’, i.e. the bandwidth of the excitation pulses for both the ESR and NMR transitions are much smaller than the spectral bandwidth. In other words, both the ESR and NMR pulses are generally selective excitation pulses. The broad linewidths also exclude certain techniques such as cross polarization in the rotating frame and magic angle spinning which have had such an important impact on NMR of solids from being directly adapted to PE NMR experiments.

The second important difference to bear in mind when comparing PE NMR spectroscopy with pulsed heteronuclear NMR is the difference in the nature of the total wavefunction associated with the electron compared with the nucleus. The electron is generally in an eigenstate, such as an atomic or

molecular orbital, which has a much greater spatial extent than the localized eigenstate which describes the nucleus. This has the consequence that the electron spin is delocalized so that the electron is generally coupled to many more nuclei than would be the case if the electron were represented by a point dipole. The delocalization of the electron spin density in molecular orbitals that have well defined spatial extents can also contribute large anisotropic components to the local (i.e. hyperfine) field. The anisotropy of the hyperfine interaction also assures that the quantization axis for the nucleus does not point in the same direction in the two electron spin eigenstates. This anisotropy in the hyperfine interaction is therefore responsible for the broad spectral widths observed for the NMR transitions and also affects the transitions which are observed, since formally forbidden transitions become ‘semiforbidden’ transitions.

Another consequence of the nature of the electronic states that host the unpaired electron is that spin coupling mechanisms such as the spin–orbit coupling are effective in broadening the ESR linewidth and in enhancing the spin relaxation rate. Both the broad lines and the shorter relaxation times have implications on the types of PE NMR experiments that can be performed.

The pulse sequences employed in PE NMR experiments can be conveniently divided into pulse periods in direct analogy to NMR spectroscopy. With the above-mentioned caveats in mind, the pulse periods can be analyzed by analogy to a pulsed heteronuclear NMR solids experiment within the soft pulse limit, wherein selective excitation is considered in the analysis. The most basic experiment consists of a preparation, mixing, and detection period. The purpose of the preparation period is to create an initial state perturbed from the equilibrium spin polarization established by the conditions of the temperature and external field (as well as by the level structure of the electron–nuclear coupled spin system). In all PE NMR experiments reported to date, one or two microwave pulses are applied to excite ESR transitions in the preparation period.

Two basically different types of PE NMR experiments will be performed depending on whether the microwave preparation pulses have created sublevel nuclear spin polarization or electron spin coherence at the end of the preparation period. The former are the starting points for ESR detected sublevel polarization transfer experiments and for ESR detected nuclear coherence experiments. The latter is the starting point for coherence transfer ENDOR experiments. In this experiment, a single microwave pulse, ideally a $\pi/2$ pulse, creates electron spin coherence in the preparation period.

In the mixing period, one or more rf pulses are applied to manipulate the sublevel polarization or sublevel coherence. The nature of the perturbation determines the type of experiment performed. The mixing period may include an evolution period, again depending on the type of experiment performed. If sublevel nuclear coherence has been created and is to be indirectly observed via the ESR transition intensity, the mixing period must end with a $\pi/2$ rf pulse that converts the sublevel coherence to sublevel polarization.

In the detection period one or more microwave pulses are applied to create electron spin coherence which is detected in the PE NMR experiment. The electron spin transverse magnetization provides a readout of the electron–nucleus longitudinal order. The transverse magnetization can be

detected by a primary spin echo,⁵⁶ a stimulated echo,⁵⁷ or as a free induction signal.⁵⁸ It is also possible to use CW irradiation to detect the transverse electron magnetization⁴² or to detect the longitudinal electron magnetization directly.²⁹

3 EXPERIMENTAL TECHNIQUES WITH SELECTED APPLICATIONS

3.1 ESR Detected Sublevel Polarization Transfer

It is possible to envisage many pulse sequences which create sublevel nuclear spin polarization. The most common methods, shown in Figure 2, are a single microwave pulse which selectively excites one ESR transition or two microwave pulses. The former was first proposed by Davies⁵⁶ and is the starting point for what has become known as the Davies ENDOR experiment. The latter was first proposed by Mims⁵⁷ and is the preparation pulse sequence for the experiment now known as Mims ENDOR.

Referring to Figure 3, the selective excitation of one of the two allowed ESR transitions converts the electron spin polarization, represented by the boxes, into electron–nucleus two-spin longitudinal order. The spin polarization from the nuclear Zeeman and hyperfine interactions is negligible compared with the electron spin polarization and can be ignored. The two spin order refers to the fact that the nuclear spins in both NMR transitions are polarized.

Two spin electron–nucleus longitudinal order can also be created using two selective microwave pulses or two nonselective microwave excitation pulses if an evolution time separates the two pulses.⁴² Sublevel polarization is created from the transverse components of the magnetization that evolves following the first pulse in the local field of the hyperfine interaction. The second pulse converts the transverse magnetization to two-spin longitudinal order. This suggests that the two pulses should be $\pi/2$ pulses for maximum efficiency in creating sublevel polarization. After the second

Figure 2 Davies ENDOR (a) and Mims ENDOR (b) pulse sequences

Figure 3 The transfer of spin polarization during the preparation (a), mixing (b) and detection (c) periods of the Davies ENDOR sequence for the four level system shown in Figure 1

pulse, the net sublevel polarization is approximately $\sin(a\tau/2) \sin(\Omega_S\tau)$, where a is the hyperfine coupling in equation (6) and Ω_S is a resonance offset. Note that no sublevel polarization exists for values $a\tau/2 = n\pi$, where n is an integer. These are known as blind spots in the Mims ENDOR experiment.

For an ESR lineshape which is inhomogeneously broadened, the sublevel polarization created by the microwave pulses in the preparation period burn a hole into the envelope of the ESR absorption lineshape as shown in Figure 4(a). The width of the hole is determined by the excitation bandwidth of the preparation pulse. In the case of two pulse excitation, a serrated pattern of magnetization is superimposed on the hole, as shown in Figure 4(b).

3.1.1 Davies and Mims ENDOR

The pulse sequences for the two most commonly used experiments for the ESR detection of sublevel polarization transfer are shown in Figure 2. The hole-burning effect created by the preparation pulses on an inhomogeneously broadened ESR absorption envelope is shown in Figure 4. The effect of a selective ESR excitation on the electron spin polarization in a four level system described by equation (7) is shown in Figure 3(a). The electron spin polarization associated with these two energy levels will be inverted if the selective microwave pulse is a π pulse. Note that the sublevel longitudinal polarization of both the upper and lower NMR sublevels are not at equilibrium at the end of the preparation period.

In the next step of the pulse sequence, an rf pulse transfers and thereby ‘mixes’ the electron spin polarization between the sublevels. This is shown in Figure 3(b) for an rf pulse on resonance with the upper sublevel. In the hole-burning picture shown in Figure 4, the sublevel polarization transfer corresponds to the transfer of polarization from within the hole to a frequency offset by the value of the hyperfine coupling. This sublevel polarization transfer occurs at frequencies corresponding to the NMR frequency shifted by the hyperfine interaction (see Section 2.1.1).

The sublevel polarization transfer could, in principle, be detected directly as an NMR signal. Indeed, this would correspond to a pulsed DNP experiment. Note, however, that the sublevel polarization transfer has also changed the electron longitudinal polarization of the two ESR transitions. The sublevel polarization transfer can therefore be detected by

Figure 4 EPR spectra of an inhomogeneously broadened line after the preparation period in the Davies ENDOR (a) and Mims ENDOR (b) pulse sequences. (Reproduced by permission of Academic Press from H. Thomann and M. Bernardo, in ‘Methods in Enzymology’, eds. J. F. Riordan and B. L. Vallee, 1993, Vol. 227, Chap. 6)

measuring the change in the ESR transition intensity. This can be accomplished using a variety of techniques, as discussed in Section 2.2. In the Davies and Mims ENDOR pulse sequences the change in electron longitudinal polarization is detected by observing the change in intensity of a primary or stimulated spin echo. This electron spin coherence is indicated by the double arrow in Figure 3(c).

The spectrum of NMR transition frequencies shifted by the hyperfine coupling, i.e. the ENDOR spectrum, usually far exceeds the excitation bandwidth of the rf pulses. The complete spectrum must therefore be recorded by incrementing stepwise the rf frequency on successive iterations of the pulse sequences shown in Figure 2. The limit of resolution in the spectrum is determined by the excitation bandwidth of the rf pulse.

The Davies ENDOR spectrum of a single crystal of malonic acid which has been irradiated by X-rays to generate carbon π radicals⁵⁹ is shown in Figure 5. The transitions at approximately 5 and 30 MHz are the two sublevel transitions associated with the α proton of the CH fragment of the $\cdot\text{CH}(\text{COOH})_2$ radical molecule. The other proton lines originate from the carboxylic protons, from coupling to protons on neighboring malonic molecules, and from overlapping ESR signals from different malonic acid radical molecules.⁵⁹ The increase in spectral resolution obtained by decreasing the excitation bandwidth of the rf mixing pulse is shown in the inset of the figure.

The relative amplitudes of the ENDOR transitions are determined by the spin Hamiltonian (as discussed in

Figure 5 Davies ENDOR spectrum of an X-ray irradiated crystal of malonic acid with rf pulse widths of 5 μ s (a) and 10 μ s (b). (Reproduced by permission of the American Chemical Society from H. Thomann and M. Bernardo, in 'Advances in Chemistry Series 229: Magnetic Resonance of Carbonaceous Solids', eds. R. E. Botto and Y. Sanada, Washington, DC, 1993, Chap. 4)

Section 2.1.2) but also by the excitation bandwidth, Δ_p of the preparation pulse. In order for a sublevel polarization transfer signal to be detected indirectly using the Davies ENDOR pulse sequence [Figure 2(a)], the condition that $\Delta_p > a$, where a is the hyperfine coupling, must be satisfied.⁵⁶ If $\Delta_p > a$, the transfer of polarization remains within the hole burned into the absorption envelope. In this case the change in electron polarization is reduced, resulting in a weaker ENDOR signal. This relationship between Δ_p and a has been referred to as 'hyperfine contrast selectivity',^{37–39} as a 'spin alignment hole',⁴¹ and as a 'self-ELDOR effect'.⁴² The relationship between Δ_p and a can be used to eliminate or reduce the overlap of ENDOR signals originating from nuclei with different hyperfine couplings.^{37–39,60}

Davies ENDOR spectra on a blue copper protein, stellacyanin,⁶¹ will serve to illustrate the application of pulsed ENDOR (and PE NMR) spectroscopy. Transition metal ions and ion clusters are found at the active site for electron transfer in metalloproteins and at the active site for substrate conversion in metalloenzymes. The electron spin echo detected ESR (ED ESR) absorption envelope recorded by plotting the intensity of the primary electron spin echo as a function of magnetic field is shown in the inset of Figure 9. A spectroscopic model for the ligand coordination structure of the Cu^{2+} ion for the high-pH form of the protein is shown in Figure 6. The hyperfine coupling frequencies for each nucleus on the copper ligands are indicated in Figure 6. The NMR transitions for nuclei in the primary ligand coordination

Figure 6 Spectroscopic model for the copper coordination structure in the high pH form of stellacyanin showing the hyperfine couplings (in MHz). (Reproduced by permission of Academic Press from H. Thomann and M. Bernardo, in 'Methods in Enzymology', eds. J. F. Riordan and B. L. Vallee, London, 1993, Vol. 227, Chap. 6)

Figure 7 Davies ENDOR spectra of stellacyanin using microwave inversion and detection pulse widths t_{mw} of 0.40, 0.20, 0.40 μ s (a) and 0.04, 0.02, 0.04 μ s (b). (Reproduced by permission of Academic Press from H. Thomann and M. Bernardo, in 'Methods in Enzymology', eds. J. F. Riordan and B. L. Vallee, 1993, London, Vol. 227, Chap. 6)

structure of the Cu^{2+} ion would be difficult to measure by any other spectroscopic technique.

The hyperfine contrast selectivity mechanism for eliminating the overlap of ENDOR lines is illustrated in Figure 7, where two Davies ENDOR spectra of stellacyanin⁶¹ are shown. When a preparation pulse with narrow excitation bandwidth is used [Figure 7(a)], the proton ENDOR lines which have small hyperfine coupling values that originate from protons on the two imidazole ligands overlap the nitrogen ENDOR lines, particularly the nitrogen line centered at roughly 8 MHz. When a larger excitation bandwidth is used [Figure 7(b)] the amplitudes for these proton ENDOR lines are significantly attenuated. The 1 : 2 relative intensities of the two ^{14}N ENDOR lines centered at 8 and 18 MHz in Figure 7(b) are in agreement with the expected intensity difference due to the hyperfine enhancement factor.^{37,38}

The proton ENDOR signals from protons with small hyperfine couplings can also be observed using preparation pulses with large excitation bandwidths with the Mims ENDOR pulse sequence. A comparison of the Davies and Mims ENDOR spectra for the stellacyanin protein is shown in Figure 8. The arrows in the Mims ENDOR spectrum indicate the positions of the 'blind spots' where no ENDOR signal is observed. The position of these blind spots in the spectrum

Figure 8 Comparison of the Davies and Mims ENDOR spectra for the stellacyanin protein. (Reproduced by permission of Academic Press from H. Thomann and M. Bernardo, in 'Methods in Enzymology', eds. J. F. Riordan and B. L. Vallee, London, 1993, Vol. 227, Chap. 6)

can be selected by the value of τ chosen in the Mims ENDOR pulse sequence. Note that the ENDOR signal for the protons with small hyperfine couplings is significantly enhanced in the Mims ENDOR spectrum. This is a consequence of the fact that a larger fraction of the electron magnetization can be sampled without suppressing the ENDOR signals from the nuclei with small hyperfine couplings.

An example of the advantage of the increased sensitivity achieved by the indirect detection scheme of the pulsed ENDOR experiment is shown in Figure 9, where the ENDOR signals from the central metal Cu^{2+} ion as well as those from all the (NMR active) ligand nuclei on the metal ligands are observed. The position in the ED ESR spectrum at which this Davies ENDOR spectrum was recorded is shown in the inset of the figure. Although the hyperfine splitting of the Cu^{2+} ion can be observed at the high-field end of the ESR spectrum, the hyperfine splittings are not resolved in the low-field region of

Figure 9 Davies ENDOR spectra of stellacyanin showing the Cu, N, and H resonances. Inset shows the position in the ED ESR spectra where the ENDOR spectra was recorded. (Reproduced by permission of Plenum Press from H. Thomann and M. Bernardo, in 'Biological Magnetic Resonance', eds. L. J. Berliner and J. Reuben, New York, 1993, Vol. 13, Chap. 7)

the ESR spectrum. Note also that the pulsed ENDOR spectrum reveals the quadrupolar splitting of the Cu^{2+} nucleus. It is not possible to measure these quadrupolar interactions in the ESR spectrum.

3.1.2 Transient Nuclear Nutations

The sublevel nuclear transient nutations can be detected indirectly with the pulse sequences in Figure 2 by incrementing stepwise the rf pulse length on successive pulse sequence iterations. An example is shown for the malonic acid radical in Figure 10. The effect of the time dependence of the signal from the electron spin-lattice relaxation during the mixing time can be eliminated by choosing a fixed, long mixing time before detection or by subtracting the signal recorded without the rf pulse applied (or with the rf frequency set to an off-resonance position in the ENDOR spectrum). The electron spin echo amplitude in the detection period oscillates with a periodicity proportional to $\cos \theta_2$ where θ_2 is the sublevel nutation angle (see Section 2.1.2). These oscillations are sometimes referred to as Rabi oscillations. The influence of the hyperfine enhancement factor on the nutation angle is evident in Figure 10.

The sublevel nutation experiment provides a method for setting the rf mixing pulse conditions to the selected nutation angle. For ESR detected sublevel polarization transfer experiments, the optimum pulse is a π pulse. For the ESR detection of sublevel coherence, the rf mixing pulse would be set for a $\pi/2$ pulse. For samples which are not single crystals and that exhibit hyperfine anisotropy, the Rabi oscillations are rapidly damped after the first period.^{37,38} Consequently, the effect on the ENDOR amplitudes due to the hyperfine enhancement can be reduced by selecting a long rf pulse length. However, this produces power broadened lines, and therefore a lower resolution in the spectrum. When two or more magnetically equivalent nuclei are coupled to the electron, harmonics may be observed in the sublevel nutation pattern.⁴² An example is shown in Figure 11. Analysis of these

harmonics provides a method for determining the number of equivalent nuclei coupled to the electron.

3.1.3 Optimized Davies and Mims ENDOR

The Davies or Mims ENDOR pulse sequences produce a maximum ENDOR enhancement of $\Delta\chi_e/\chi_e = 1$. A pulse scheme for theoretically increasing this efficiency to $\Delta\chi_e/\chi_e = 2$ has been proposed and demonstrated.⁴² This is accomplished by inserting a microwave π pulse and a second rf π pulse following the first rf π pulse in the mixing period. This pulse sequence is the pulsed analog of the Special TRIPLE resonance technique which was also introduced to improve the efficiency in the CW ENDOR experiment.^{34,62,63} In practice, the improvement in efficiency of the Davies or Mims ENDOR signal intensity is much smaller than theoretically possible, primarily because of pulse imperfections. Nevertheless, a gain in ENDOR enhancement is observed, as shown in the example given in Figure 12. Nonideal nutation angles due to pulse imperfections are particularly problematic for noncrystalline samples where the ENDOR lines are significantly overlapped.

3.1.4 Electron–Nucleus Coherence Effects

Electron–nucleus coherence effects can be observed in the Davies ENDOR experiment if the microwave pulses in the detection period excite both allowed and semiforbidden ESR transitions.^{38,37} These coherence effects generate a nuclear modulation on the envelope of the primary electron spin echo in the detection period analogous to the ESEEM experiment. An example of this phenomenon is shown in Figure 13 where two Davies ENDOR spectra for the blue copper protein,

Figure 12 Mims-ENDOR spectra (a) of Cu(II)-doped TGS single crystal around the proton transition at $\omega_p/2\pi = 10.15$ MHz and the optimized spectra obtained using the pulse sequence described in the text. stellacyanin, are shown recorded for two different values of the spin echo delay time τ in the detection period. The values of τ used in the detection period are indicated on the echo envelope waveform shown in the inset. These coherence effects can have important consequences for the analysis of the ENDOR spectrum. Note that the relative amplitudes of the ENDOR intensities depend on the value of τ in the detection period. This effect can be used as a spectral editing technique.^{38,37}

3.1.5 Electron–Nucleus–Nucleus Triple Resonance

The Double ENDOR was originally introduced as a CW ENDOR technique to establish the connectivity of hyperfine sublevels and to determine the relative signs of the hyperfine interaction for nonequivalent nuclei.^{63,64} The pulsed implementation of the Double ENDOR experiment is shown in Figure 14.⁴¹ The experiment is analogous to the Davies ENDOR experiment, except that a second rf π pulse is inserted in the mixing period to irradiate a preselected ENDOR transition. The Double ENDOR difference spectrum, obtained from the difference between the ENDOR and Double ENDOR spectrum, identifies any changes in intensities of the ENDOR transitions induced by pumping at the second rf frequency. A peak in the Double ENDOR difference spectrum will only be

observed if the two sublevels each have a level in common with the ESR transition.

An example of the pulsed Double ENDOR and Double ENDOR difference spectrum recorded for the radical in the conjugated conducting polymer, polyacetylene, is shown in Figure 15.⁴¹ The Double ENDOR difference spectra indicate that the unpaired electron is coupled to protons with both positive and negative hyperfine interactions. In this case, similar conclusions were obtained using the CW Double ENDOR experiment and the results were used to determine an electron–electron correlation energy using a Hartree–Fock molecular orbital calculation.⁶⁵ However, the CW Double ENDOR experiment was only successful over a restricted temperature range, which is not the case for the pulsed version of the experiment. The pulsed Double ENDOR experiment has also been applied to studies of the irradiated malonic acid radical molecule^{45, 43} and to studies of the coordination

structure of transition metal ions and metal clusters in metalloenzymes.³⁸

3.1.6 Electron–Nucleus–Electron Triple Resonance

Another variation of a pulsed triple resonance experiment is shown in Figure 16.^{38, 37} This experiment is related to the Davies ENDOR experiment, except that the frequency of the detection pulses are offset by a frequency Δ from the frequency of the preparation pulse. This is shown schematically in Figure 17 by the magnetic positions at which the preparation, indicated by B_p , and detection, indicated by B_d , irradiation pulses are applied within the ESR absorption envelope. Sublevel polarization transfer that connects the positions B_p and B_d must originate from rf driven sublevel NMR transitions. Polarization transfer by mechanisms other than rf driven nuclear spin flips, such as by spin diffusion, are ineffective because of the short time interval between the preparation and detection period. The value of Δ therefore preselects nuclei with the hyperfine coupling $A = \Delta$. For this reason, the ENDOR spectrum generated for $\Delta = A$ is referred to as a hyperfine selective (HS) ENDOR spectrum. An HS ENDOR spectrum can also be generated by jumping the applied magnetic field.⁴²

The HS ENDOR technique is illustrated in Figure 18. The Davies ENDOR spectra for the blue copper protein, stellacyanin, recorded for the native pH 7 form of the protein and for the high-pH (pH 11) perturbed blue form of the protein are shown in Figures 18(a) and 18(b), respectively. The spectra are identical except for the intensity of a transition at 21 MHz observed in the spectrum of the high-pH form. The assignment of this peak is facilitated using the HS ENDOR experiment, as

Figure 16 Pulsed electron–nucleus–electron triple resonance pulse sequence. (Reproduced by permission of Academic Press from H. Thomann and M. Bernardo, in ‘Methods in Enzymology’, eds. J. F. Riordan and B. L. Vallee, London 1993, Vol. 227, Chap. 6)

illustrated by the three HS ENDOR spectra recorded for values of $\Delta = 19, 42$, and 36 MHz, which are shown in Figures 18(c), 18(d) and 18(e) respectively.

3.2 EPR Detected Sublevel Nuclear Coherence

Sublevel coherence can be created by a $\pi/2$ rf pulse applied at the end of the preparation period. Once created, this sublevel coherence can be manipulated in analogy to many other solid state NMR experiments. Specific examples of these type of experiments are described in this section.

3.2.1 Nuclear Free Induction

The evolution of the sublevel coherence under free precession in the local field can be detected indirectly using the pulse sequence shown in Figure 19.^{41,43} The frequency of the rf pulses are set to excite a transition in the ENDOR spectrum. The sublevel coherence evolving during the evolution time t_1 is converted back to electron spin longitudinal polarization by a second rf $\pi/2$ pulse. The sublevel coherence signal at evolution time t_1 is then detected indirectly from the intensity

Figure 18 Davies ENDOR spectra of the native (pH 7) form (a) and the high-pH (pH 11) form (b) of stellacyanin. HS ENDOR spectra of the high pH form with $\Delta = 19.0$ (c), 42.0 (d), and 36 (e) MHz were used to assign the feature at 21 MHz to nitrogen. (Reproduced by permission of Academic Press from H. Thomann and M. Bernardo, in ‘Methods in Enzymology’, eds. J. F. Riordan and B. L. Vallee, London, 1993, Vol. 227, Chap. 6)

modulation of the primary electron spin echo in the detection period. The sublevel free induction signal is then detected point by point by incrementing t_1 on successive pulse sequence iterations. Both the in-phase and phase-quadrature sublevel free precession signals can be detected by phase shifting the relative phase of the two rf pulses by $\pi/2$. Additional phase cycling by π can be used to cancel the effects of electron spin–lattice magnetization recovery during the t_1 evolution period. The rf pulse excitation bandwidth is usually much smaller than the spectral spread of the ENDOR spectrum. In order to record the entire ENDOR spectrum, the pulse sequence shown in Figure 19 must be repeated with the rf frequency incremented on successive experiments. A spectral slice of the overall ENDOR spectrum, determined by the bandwidth of the rf excitation pulse, is recorded for each selected rf. The whole ENDOR spectrum is reconstructed by adding the slices of the limited spectral regions recorded in each experiment.

The ESR detected sublevel free precession experiment is illustrated in Figure 20. These data are collected for a crystal of irradiated malonic acid. In the Davies ENDOR spectrum, a transition that shows no evidence of fine structure is observed at 14.42 MHz. The in-phase and phase-quadrature sublevel free precession signals recorded using the pulse sequence in Figure 19 and the procedure described above are shown in Figure 20(a). The complex Fourier transform of these waveforms is shown in Figure 20(b). This spectrum indicates that the ENDOR line is composed of three overlapping

Sanada, Washington, DC, 1993, Chap. 4)

transitions which are not resolved in the Davies ENDOR spectrum.

3.2.2 Multiple Quantum Electron–Nucleus Coherence

The coupling of two or more nuclei with equivalent hyperfine couplings can be detected indirectly using the pulse sequences shown in Figure 21.^{41,66} The sublevel polarization can be created using either the inversion–recovery technique with primary spin echo detection (i.e. as in the Davies ENDOR pulse sequence) or by the two pulse excitation in the preparation period with a single pulse in the detection

Figure 21 Multiple quantum (MQ) ENDOR pulse sequences: Davies MQ ENDOR (a) and Mims MQ ENDOR (b). (Reproduced by permission of Laser Pages Publishing from H. Thomann and M. Bernardo, *Isr. J. Chem.*, 1992, **32**, 323)

period to create a stimulated echo (i.e. as in the Mims ENDOR pulse sequence). An n -quantum sublevel coherence is detected using the phase incrementation technique in analogy to the NMR experiment.^{53,67} An n -quantum coherence accumulates a phase $\theta_n = n\omega_{\text{ENDOR}}t_{\text{evol}}$ where t_{evol} is an evolution time and ω_{ENDOR} is the sublevel transition frequency.

In the present experiments the phase accumulation occurs during the nutation of the sublevel polarization so that $t_{\text{evol}} = t_{\text{p}}^{\text{rf}}$. This phase accumulation can be detected by incrementing the phase of the rf mixing pulse in the middle of the mixing period. Theoretically, the optimum ENDOR signal is obtained by applying two $\pi/2$ rf pulses. Each point on the plot of the phase interferogram is collected by incrementing the phase of the second rf pulse on successive pulse sequence iterations.

An example of a multiple quantum spectrum recorded using the pulse sequence in Figure 21(a) for the malonic acid radical molecule is shown in Figure 22.⁶⁶ Multiple quantum coherences up to $n = 3$ are observed for an ENDOR transition at 14.42 MHz recorded for the malonic acid radical molecule in a crystal at an arbitrary orientation. This is consistent with the three lines observed in the ESR detected sublevel FID spectra recorded under identical conditions [Figure 20(b)]. Multiple quantum spectra recorded for several evolution times for free precession are also shown in Figure 22. The oscillation for each order of coherence originates from the free precession of transverse sublevel magnetization in the presence of the local field.

3.2.3 Nuclear Spin Echoes

Hyperfine sublevel spin echoes can be created and detected indirectly by inserting a refocusing rf pulse in the evolution period of the mixing period for the pulse sequence shown in Figure 20. The pulse sequence for this indirect detection of sublevel spin echoes is shown in Figure 23.^{40,41} The first rf pulse in the mixing period creates sublevel coherence. This coherence evolves under free precession for time τ_n and is

Figure 22 Davies multiple quantum ENDOR spectra of the malonic acid radical for various evolution times. (Reproduced by permission of Laser Pages Publishing from H. Thomann and M. Bernardo, *Isr. J. Chem.*, 1992, **32**, 323)

Figure 23 Pulse sequence for EPR detection of sublevel spin echo. (Reproduced by permission of the American Chemical Society from H. Thomann and M. Bernardo, in 'Advances in Chemistry Series 229: Magnetic Resonance of Carbonaceous Solids', eds. R. E. Botto and Y. Sanada, Washington, DC, 1993, Chap. 4)

then refocused by the rf π pulse. The sublevel spin echo formed at time τ_n after the refocusing pulse can be detected by incrementing the time t_1 of the third rf mixing pulse. The third rf pulse transforms the sublevel coherence into two spin electron-nucleus longitudinal order. This is transformed to electron spin coherence for detection of the electron spin polarization by the microwave pulses in the detection period.

The sublevel echo can be detected point by point by incrementing the value of t_1 from $t_1 < \tau_n$ to $t_1 > \tau_n$ on successive pulse sequence iterations. In each pulse sequence iteration the sublevel coherence is detected by the change in intensity of the electron spin echo in the detection period. An example of sublevel spin echoes detected by this procedure for an X-ray irradiated malonic acid crystal are shown in the inset of Figure 24. The two sublevel spin echoes shown were recorded for τ_n values of 5 and 20 μ s.

The circles shown in the inset of Figure 24 indicate the echo envelope intensities recorded for several values of $t_1 = \tau_n$. The full sublevel spin echo decay envelope along with a fit to a single exponential and the residuals for the fit are also shown in Figure 24. These sublevel echoes and envelope decay were recorded for the $\nu_+ = 30.19$ MHz ENDOR transition. This corresponds to the proton NMR transition for the α proton of the $\cdot\text{CH}(\text{COOH})_2$ radical molecule which is shifted to the high-frequency side of the proton Larmor frequency. The sublevel T_{2n} decay time obtained from the single exponential fit shown

Figure 24 The sublevel spin echo decay recorded with $t_1 = \tau_n$ along with the fit to a single exponential and the residuals of the fit. (Reproduced by permission of the American Chemical Society from H. Thomann and M. Bernardo, in 'Advances in Chemistry Series 229: Magnetic Resonance of Carbonaceous Solids', eds. R. E. Botto and Y. Sanada, Washington, DC, 1993, Chap. 4)

in Figure 24 is 60 μ s. The proton T_{2n} values measured for $\nu_{\text{rf}} = \nu_n$ are shorter than the values measured at frequencies shifted away from the proton Larmor frequency.

Similar results have been obtained in sublevel nuclear T_{2n} studies of protons in coal samples.⁴⁶ In these coal studies, the ESR detected sublevel T_{2n} values measured at $\nu_{\text{rf}} = \nu_n$ were similar to the value measured directly by NMR.⁶⁸ The ESR detected sublevel T_{2n} values increased for NMR transitions shifted further away from the proton Larmor frequency. Apparently the time-dependent local magnetic field from the hyperfine interaction is not an effective sublevel T_{2n} relaxation mechanism. The T_{2n} value measured directly by NMR is determined by the proton homonuclear dipolar coupling. The equivalence of the value measured in the ESR detected sublevel T_{2n} experiment for $\nu_{\text{rf}} = \nu_n$ suggests that the T_{2n} value is also determined by the proton dipolar interaction with the hyperfine coupling serving only as a mechanism for detecting the sublevel coherence signal. Quite different results can be expected if the time dependence of the local field is an effective T_{2n} mechanism. In this case the T_{2n} values would be expected to decrease as the NMR transition frequency is shifted away from the proton Larmor frequency.

3.3 Coherence Transfer ENDOR

In analogy to the coherence transfer experiments known in NMR spectroscopy, it is also possible to detect the hyperfine sublevel transitions by an electron-nuclear double resonance coherence transfer experiment.^{41,43,69} Three different pulse sequences for coherence transfer ENDOR experiments are shown in Figure 25. The basic principle in all three types of experiment is similar. The rf pulses applied during the period of free precession of the electron spin coherence created by a $\pi/2$ microwave pulse interfere with the refocusing of this electron coherence following the microwave π pulse.

Figure 25 Pulse sequences for coherence transfer ENDOR

This occurs if the rf pulse is on resonance with an NMR transition that has a sublevel in common with the electron spin eigenlevel that belongs to the states from which the electron spin coherence was created. In this case, the sublevel NMR transition shifts the phase of the electron spin coherence which is detected as an attenuation of the electron spin echo. If the rf pulse is a π pulse the electron spin echo intensity is reduced to zero resulting in $\Delta\chi_e/\chi_e = 1$. If the rf pulse is a 2π pulse, the echo intensity changes sign resulting in $\Delta\chi_e/\chi_e = 2$. If a 4π pulse is applied, the electron spin echo intensity returns to its original intensity. This response of the electron spin echo intensity to the rotational symmetry of the sublevel nutation angle is called the ‘spinor property’ and is a property of wavefunctions for spin- $\frac{1}{2}$ particles.

The ENDOR spectrum recorded using the pulse sequence shown in Figure 25(a) is sufficient to observe the coherence transfer ENDOR effect. However, the application of a single rf pulse also produces a large Bloch–Siegert (BS) frequency shift $\omega_{BS} = -\gamma_e(B_2^2/B_0)$, which results in a phase shift of $\omega_{BS}t_p^{rf}$. Since the rf magnetic field strength is not constant as a function of frequency across the ENDOR spectrum, the Bloch–Siegert phase shift is observed as a broad feature, as shown in Figure 26(a), which can mask the ENDOR transitions. The Bloch–Siegert phase shift can be refocused by applying a second rf pulse, as shown in Figure 25(b), which is symmetrically displaced about the microwave refocusing pulse. This eliminates the broad feature in the ENDOR spectrum as shown in Figure 26(b). The maximum ENDOR effect of $\Delta\chi_e/\chi_e = 1$ is observed when the two rf pulses are π pulses. The efficiency of the ENDOR effect can theoretically be increased to $\Delta\chi_e/\chi_e = 2$ if the two rf pulses are 2π pulses but with a 90° shift introduced, as shown in Figure 25(c).^{41,43} The enhancement in the ENDOR signal intensity is shown in Figure 26(c). In practice, the ENDOR efficiency is improved for this phase shifted spinor ENDOR pulse sequence, but because of technical limitations (primarily pulse imperfections) the increase in efficiency is much smaller than theoretically expected. Another limitation of coherence transfer ENDOR experiments is that the ENDOR lines are usually power broadened because of the short electron phase memory time encountered for most samples. It is rare that phase memory times are longer than a few microseconds, even at liquid

Figure 26 Coherence transfer single crystal ENDOR spectra of the malonic acid radical recorded with corresponding pulse sequences shown in Figure 25. (Reproduced by permission of the American Chemical Society from C. Gemperle and A. Schweiger, *Chem. Rev.*, 1991, **91**, 1481)

helium temperatures. Nevertheless, the coherence transfer ENDOR experiment has revealed fundamentally interesting properties of the spin dynamics of the electron–nucleus spin system.

4 CONCLUDING REMARKS

ENDOR and the extension to PE NMR spectroscopy are presently tools of the specialist. They are very powerful techniques in specific cases where the spectra and/or spin dynamics for the nuclei of interest are strongly influenced by the large local magnetic fields originating from the hyperfine coupling with unpaired electron spins. In such cases the NMR transition frequencies are shifted by very large values when compared with NMR spectra of diamagnetic samples. When these circumstances do apply, ENDOR and PE NMR spectroscopy are often the only techniques which can provide the desired information. In this review we have included examples of applications in organic solids, metallobiochemistry, and organometallic chemistry. With the introduction of pulsed excitation techniques, extension to multiple irradiation frequencies, and the introduction of commercially available pulsed instrumentation, continued development of the methodology and an increasing range of applications can be expected for these techniques in the near future. Recent developments in high-frequency ESR,⁷⁰ including the extension to high-frequency ENDOR,⁷¹ will also likely expand the range of research applications. The combination of pulsed ESR and pulsed NMR should continue to be a vibrant area of research as new technology becomes available and as new methodologies and applications are developed.

EPR and In Vivo EPR: Roles for Experimental and Clinical NMR Studies

Harold M. Swartz and Goran Bačić

Dartmouth Medical School, Hanover, NH, USA

1 INTRODUCTION

1.1 Scope and Rationale of Coverage

The use of electron paramagnetic resonance (EPR or, completely equivalently, electron spin resonance) in biomedicine is a vast and still developing subject, with many areas of direct or indirect relevance to the subject of this volume (related articles are listed at the end of the text). We will not, however, attempt to cover all of these topics but instead will restrict our discussion to four topics that are especially important to the use of MRI and MRS in vivo for experimental and clinical purposes:

1. measurement of the concentration of oxygen, especially in tissues in vivo;
2. measures of redox metabolism and/or distribution of drugs;
3. measurement of the viability of cells;
4. measurement of the concentration and distribution of contrast agents, especially in vivo.

These topics were chosen because they are areas of great importance for the use of NMR in biomedicine and are measurements for which EPR techniques can provide critically needed information that cannot be obtained as easily and/or as well by other techniques, including NMR. Our coverage of these topics will focus on overviews of the current status and the likely future developments; we will not attempt to provide extensive reviews of the rapidly expanding literature on these subjects (see¹⁻⁵ for recent reviews).

The measurement of the concentration of oxygen in cells and tissues, with an emphasis on the determination of hypoxia, seems especially important. Many of the uses of NMR, especially spectroscopy, really are aimed at making such measurements, and/or studying phenomena that are very dependent on the concentration of oxygen. This is certainly the case for most phosphorus NMR studies, which usually are aimed at measurements of the redox sensitive concentrations of phosphorus metabolites. Similarly much of proton NMR spectroscopy is aimed at measurements of intermediates such as lactic acid which reflect the concentration of oxygen in the tissues and, indeed, in many cases these measurements are used to provide indirect measures of the extent of hypoxia because more direct measurements are not available. As we will see EPR can make very sensitive and accurate measurements of the concentration of oxygen in tissues but it cannot, as yet, achieve the depth of penetration and the spatial resolution of NMR imaging. As a consequence, there is a great potential for the combined use of EPR and NMR in which the

EPR techniques provide the needed determinations of the relationships between NMR spectroscopic measurements and the actual concentrations of oxygen. Such data will then make it much more feasible to use NMR techniques to obtain accurate insights into the state of oxygen dependent metabolism and therefore better address the diagnosis and therapy of diseases in which hypoxia plays a significant role (e.g. cancer, ischemia, and inflammation).

From the preceding discussion it seems evident that to the extent that EPR can provide additional measures of metabolism, beyond the direct measurement of the concentration of oxygen, EPR will further complement NMR measurements significantly. The metabolism of nitroxides appears to provide such a measure. EPR also can be used to follow the distribution and metabolism of some drugs, which can provide additional information on redox metabolism as well as pharmacokinetics. These studies are feasible through the use of metabolizable paramagnetic spin labels which are either the objects of interest themselves or attached to drugs, etc. as labels which then can be followed selectively by EPR.

The measurement of the viability of cells by EPR, while still at an early stage of development, provides an essentially unique capability that is very complementary to NMR studies. At the present time the results of this approach are available only in aggregates of cells (spheroids) and isolated cells. In the former they provide perhaps the most advanced and effective applications of EPR imaging (EPRI) in a biological system.

The use of EPR to study NMR contrast agents in many ways is very straightforward and logical, although it has not been applied as widely as would seem desirable. Virtually all NMR contrast agents are active because they have unpaired electrons and therefore they are directly observable by EPR. This is so because EPR sensitively and exclusively responds to electronic magnetic moments; usually those associated with unpaired electrons. While this approach has been very productive for the study of some NMR contrast agents such as the nitroxides, there are some significant limitations in the application of this technique in vivo to many of the metal ion based contrast agents due to unfavorably short relaxation times and/or spectral features. (The metal ion contrast agents, of course, can be studied very effectively by EPR in vitro.)

1.2 Brief Summary of the Principles of EPR Applied to the Study of In Vivo Systems

Although there are few fundamental differences between the principles of electron and nuclear magnetic resonance, differences in physical and chemical properties of the resonant species (unpaired electrons vs. nuclei with net spin) lead to profound differences in the techniques that are used to record spectra. Perhaps the greatest differences arise because the gyromagnetic ratio of an unpaired electron is ~700 times larger than that of a proton, so the resonance frequency/magnetic field ratio for the electron is 28 GHz T⁻¹, vs. 42.5 MHz T⁻¹ for the proton. Consequently, standard EPR spectrometers operate at much higher frequencies and lower fields than conventional NMR spectrometers. While EPR spectroscopy is now performed using a wide range of frequencies from rf to far-infrared, most standard, commercial EPR spectrometers operate

at 9.5 and 35 GHz (X- and Q-band). At these frequencies non-resonant absorption of the electromagnetic radiation by the liquid water in biological systems presents a serious problem, thus limiting the sample size to a thickness of less than 1 mm. Larger aqueous samples or animals can be studied only by reducing the operating frequency to 1 GHz or less, but, of course, this results in reduced sensitivity. To date most of the published successful applications of in vivo EPR techniques to actual biomedical problems have used spectroscopy rather than imaging and have been done at 1 GHz (L-band). Several groups are investigating the feasibility of extending these approaches to imaging and/or lower frequencies, but sensitivity may be a limiting factor. The use of lower frequencies (e.g. 300–500 MHz) would be especially attractive because this would extend the sensitive depth from about 10 mm to about 70 mm.

The lack of sufficient amounts of naturally occurring paramagnetic materials is another potential source of problems. Both direct observations and theoretical calculations show that endogenous paramagnetic species such as paramagnetic metal ions and free radicals are present in insufficient concentrations to be detected directly by EPR in vivo.⁴ (The only naturally occurring exception is the polymer, melanin.⁴) This presents an obvious problem since the paramagnetic substance has to be introduced, which can cause problems with regard to sensitivity and, potentially, toxicity. However, this has some beneficial aspects, since the only paramagnetic species that will be observed in vivo will be those introduced by the experimenter. The absence of background signals is particularly convenient for in vivo EPR spectroscopy (e.g. in contrast to proton spectroscopy where water suppression is required). With the addition of appropriate paramagnetic species the sensitivity of EPR, on a molar basis, is 700 times greater than for NMR. Paramagnetic species which are very stable and have appropriate lineshapes have been developed recently and these have been a significant factor in the successful development of in vivo EPR techniques.⁴

The short relaxation times of most paramagnetic species can be an additional potential source of problems. The timescale of electron spin relaxation of most paramagnetic species is nanoseconds (in contrast to NMR where the relaxation times typically are milliseconds); consequently, essentially all in vivo studies have been done using CW-EPR and have not been able to utilize most of the pulse techniques developed for NMR in biological systems. At the same time, the large widths of EPR resonance lines necessitate the use of high magnetic field gradient strengths for imaging that are at least one order of magnitude greater than those used in NMR imaging. Additional problems for EPRI arise from the fact that the EPR spectra of most paramagnetic species have multiple lines and multiple lineshapes; these spectral features, however, can be very valuable for EPR spectroscopy because they can provide very sensitive parameters of the environment in which the paramagnetic species are located.

As a consequence of the above factors the development of in vivo EPR techniques, especially imaging, has not occurred as rapidly as with NMR. Recently, however, there has been a significant increase of productivity in these areas, especially with in vivo spectroscopy. The emphasis on spectroscopy vs. imaging has not turned out to be a very significant limitation

because the most useful applications of EPR in vivo can probably be achieved best by localized spectroscopy.

To date almost all of the in vivo EPR studies have been done with small animals and there are only two reports of human studies. It appears very likely, however, that rapid progress will occur in the next few years, because of the very promising data which have been obtained recently, especially in regard to oximetry.

1.3 Experimental Considerations

The first EPR experiment conducted by Zavoisky in 1944⁶ was performed at 133 MHz. With the development of commercial EPR spectrometers the usual frequency was raised by 2–3 orders of magnitude to increase sensitivity, but this simultaneously reduced the size of nonfrozen aqueous samples that could be studied by standard cylindrical or rectangular EPR cavities to less than 1 mm, due to an increase in the nonresonant absorption of microwave by aqueous samples, thus considerably limiting applications of EPR to biological systems. In the first in vivo EPR study performed in 1975 at 9 GHz (X-band) these limitations were avoided by implanting a helix antenna into the rat liver,⁷ and more recently in vivo EPR studies in small animals have been carried out at 9 GHz by inserting the tail into the cavity. The obvious constraints of such approaches eventually led to the development of low-frequency EPR instruments, thus increasing the ability to penetrate deeper into biological tissues; however, it took almost 10 years before the next studies aimed at in vivo EPR were performed.^{8,9} Subsequently developments have occurred at an ever-increasing rate and have led to a number of very productive applications of in vivo EPR techniques. The key technical advances occurred in four areas: development of low-frequency EPR spectrometers suitable for use with living objects,^{10–14} development of detectors suitable for in vivo studies,^{15,16} recognition and development of paramagnetic species with properties suited for particular applications (especially the measurement of pO_2),¹⁷ and improved methods for data acquisition and analysis.^{18–21} Limitations of space prevent us from describing these developments in detail here, but they are illustrated in the following descriptions of applications and further details are available in the references that are cited.

While these developments have greatly expanded the use of EPR in living subjects, some fundamental limitations remain and therefore the application of EPR techniques to clinical medicine is unlikely to reach the extent of NMR techniques. Probably the key factors are a combination of depth of penetration and sensitivity. These are, of course, related because in order to achieve greater depth of penetration of the microwaves one must decrease the frequency and this inevitably leads to decreased sensitivity. Many of the principal uses of EPR in vivo are likely to occur with the use of frequencies around 1 GHz. At 1 GHz there is relatively high sensitivity but the practical limit for depth is about 10 mm. This can be partially overcome by the use of catheters, etc. to insert the detector deeper into the body. If the frequency is reduced to 300–500 MHz the practical limits on depth increase by a factor of up to 10 but there is a concomitant decrease in sensitivity. Very useful data have already been obtained in experimental animals with in vivo EPR at both ends of these frequency ranges, and feasibility studies have been successful in human subjects, so it

is therefore clear that EPR will be quite useful *in vivo*. The extent of the usefulness of *in vivo* EPR seems certain to be extended by combining it with complementary approaches such as NMR.

2 MEASUREMENT OF THE CONCENTRATION OF OXYGEN, ESPECIALLY IN TISSUES *IN VIVO*, BY EPR OXIMETRY

One of the most effective and rapidly developing uses of EPR in biological systems is the measurement of pO_2 . The importance to NMR of these measurements rests on (a) the profound role of oxygen in many physiological and pathophysiological processes (ischemic diseases, reperfusion injury, response of tumors to therapy, etc.); (b) the lack of an adequate alternative methodology to make accurate *in vivo* measurements under biologically pertinent conditions (these conditions include making the measurements directly in the tissues, at the relatively low concentrations of oxygen which occur in tissues *in vivo*); and (c) the suitability of NMR techniques, especially spectroscopy, to measure metabolites whose concentrations and importance are linked closely to pO_2 .

The term EPR oximetry encompasses a number of distinct experimental techniques; however, most of these methods rely on the paramagnetic properties of molecular oxygen. The ground state of oxygen has two unpaired electrons and a very rapid relaxation rate, which via Heisenberg spin exchange between oxygen and other paramagnetic species provides an efficient relaxation mechanism for the latter. As a consequence, the presence of oxygen has an effect on both T_1 and T_2 of spectra and these effects can be followed quantitatively by a variety of spectral parameters (e.g. linewidth, resolution of superhyperfine structure, and microwave power saturation). An NMR counterpart of this type of oximetry uses the effect of oxygen on the spin-lattice relaxation time of ^{19}F in tissues preloaded with fluorine compounds.

The use of EPR to measure the concentration of oxygen in biological samples was introduced more than 20 years ago and while it has been a useful technique for many studies of model systems and cells, it is only recently that it has been applied successfully *in vivo*. The latter applications have been very successful because of the development of new techniques and new oxygen sensitive paramagnetic materials. Some of the latter appear to have properties that are virtually ideal for the measurement of the concentration of oxygen in tissues *in vivo*, including a high degree of chemical and physical stability, essentially complete inertness in tissues, an apparent lack of toxicity, high sensitivity to the concentration of oxygen, and retention of their response to oxygen for periods of years or longer.²²

There are two principal types of oxygen sensitive materials which are now available for the direct measurement of pO_2 in biological systems: soluble, stable free radicals (especially nitroxides and their derivatives), and stable paramagnetic particles with oxygen sensitive spectra (especially fusinite coal, lithium phthalocyanine, India ink, and chars of carbohydrates). Each of these has properties that may be especially useful for particular applications and, in aggregate, they provide a versatile and effective set of approaches to measure the concentration of

oxygen under most or all conditions that are likely to occur experimentally and clinically.

The use of particulate materials has already led to some very useful data on pO_2 *in vivo*.²²⁻²⁶ These materials share several very desirable properties for such studies including:

1. relative noninvasiveness and repeatability (after an initial placement of the paramagnetic materials, measurements can be made noninvasively as frequently as desired over a period of a year or more);
2. sensitivity (measurements can, at low pO_2 , resolve differences of the order of 0.1 torr);
3. accuracy (repeated measurements have a small variability and correlate closely with measurements of pO_2 by other methods);
4. provide localized measurements (the spatial resolution is the same as the size of the paramagnetic particles, which can be as small as a single particle of less than 0.2 mm in diameter. At the same time, accurate localization of the probe can be achieved using MR imaging);²⁴
5. capability of making several measurements simultaneously (this is accomplished by inserting multiple discrete solid particles and applying a magnetic field gradient such that sites less than 1 mm apart can be resolved);²⁵
6. little or no effects of chemical and physical conditions likely to be encountered in viable biological systems (changes in pH or the presence of oxidants, reductants, or other paramagnetic materials do not affect measurements of pO_2);
7. little or no toxicity (the paramagnetic materials are very inert in biological systems as assayed in both cell culture and *in vivo*);
8. capability of following changes in pO_2 with a time resolution of seconds or less;
9. response to pO_2 (in contrast to nitroxides and other oxygen sensitive materials which may respond to the concentration of oxygen or a product of concentration and the rate of diffusion).

The organs that have been studied by this approach include brain, heart (both *in situ* and as isolated perfused systems, especially the Langendorf preparation), lung, liver, kidney, skeletal muscle, and joints. These approaches have also been applied to the study of several important pathological and physiological conditions including tumors, ischemia, inflammation, and anesthesia.

The capabilities of these approaches are indicated in Figure 1 which shows the change in pO_2 in tumors as a function of time and therapeutic irradiation. The ability to resolve small changes in pO_2 (less than 0.2 torr) in unanesthetized animals provides a powerful tool for understanding and interpreting NMR spectroscopic studies of this type of system.

While it appears that many studies in the future will utilize the oxygen-sensitive particulate paramagnetic materials, there also are a number of very effective uses of the nitroxides in measuring pO_2 (in general the nitroxides actually measure the product of the concentration of oxygen and the rate of diffusion but this measurement can usually be converted directly to pO_2 under most experimental conditions). EPR oximetry with nitroxides can utilize both the physical and the physiological effects of oxygen, and its application to cellular systems has been extensively reviewed and will not be considered further here.

Figure 1 In vivo EPR measurements of changes of pO_2 as measured by India ink in a mouse tumor (mammary adenocarcinoma) after a single dose of radiation (20 Gy)

The nitroxides have also been used for oximetry in larger systems, including intact animals. The results of these studies, while very promising, have not yet been applied to the direct study of pathological processes, although they have produced some very exciting data on pO_2 in perfused hearts and some promising data on in vivo systems.^{11,27–29} The advantages of nitroxides for such studies includes their versatility (nitroxides can be synthesized with virtually any chemical and physical properties) and that they are usually available as soluble materials that can diffuse throughout the system. Their potential disadvantages include a tendency to undergo bioreduction and their relatively weaker response to changes in pO_2 (it seems unlikely that they will be able to resolve changes of less than 5 torr in vivo).

Nitroxides have also been used in extended systems where EPR imaging or in vivo EPR spectroscopy were used to study the concentration, distribution, and diffusion of oxygen in macroscopic biological samples. Several experiments have been performed on small samples with higher frequency EPR (9 GHz) using one-dimensional (1D) and two-dimensional (2D) EPR. 1D EPR imaging is based on the use of conventional EPR spectroscopy in the presence of a unidirectional linear magnetic field gradient. The obvious restriction is that the sample has to possess a high degree of symmetry and/or isotropic properties; however, 1D EPR allows rapid accumulation (e.g. 2 s per spectrum) and is particularly suitable for studying fast diffusion processes such as diffusion of oxygen. Interaction of oxygen with nitroxides shortens relaxation times; hence the diffusion of oxygen can be measured in samples preloaded with oxygen sensitive paramagnetic species. To illustrate this approach, fast 1D EPRI has been used to follow oxygen diffusion in aqueous media³⁰ and the results agree well with the value of the oxygen diffusion coefficient measured by classical methods.

A few 2D EPRI experiments have been reported, including studies to examine the feasibility of visualizing the distribution of oxygen in model and biological samples and the basic mechanisms for the contrast enhancement.^{31,32} The effects of

oxygen on the relaxation times of nitroxides (analogous to the action of paramagnetic agents on proton relaxation) were utilized for contrast enhancement. Shortening of T_2 of the nitroxides causes line broadening and a concomitant decrease of line height, while shortening of T_1 induces differences in microwave power saturation. Using proper selection of EPR imaging parameters, both effects can be utilized to produce either positively or negatively enhanced oxygen dependent images.³¹ Other properties such as differential solubility of oxygen in lipophilic and hydrophilic environments also can be used to distinguish different regions of the tissue. This was demonstrated on a tissue slice containing fat and muscle regions, all of them containing the same amount of nitroxide, but they have different intensities in the image due to the higher concentration of oxygen in fat-rich areas.³²

Although EPR imaging can give insights on the distribution of oxygen it is probably not suitable for precise and direct measurements of pO_2 . Such measurements will probably require a form of spectral-spatial imaging, where the EPR spectrum can be displayed as a function of spatial localization.^{18,19,33} This considerably increases the time required for the measurement. The feasibility of doing spectral spatial oximetry has been explored in model systems.³³ It is not clear whether sufficient sensitivity can be achieved to apply this technique to animals, but it does appear to be very promising for the study of detailed distribution of pO_2 in systems amenable to study at higher frequencies, especially the tumor model, spheroids, at 9 GHz.

3 MEASURES OF REDOX METABOLISM AND/OR DISTRIBUTION OF DRUGS BY EPR

There are several interrelated approaches, based on nitroxides (although in principle other metabolizable, stable free radicals could also be used), that provide data on redox metabolism and the distribution of drugs which should be very complementary for NMR studies.

The oxygen dependent metabolism of nitroxides has been advocated as an approach to the measurement of pO_2 and redox metabolism.³⁴ Functional biological systems can reversibly reduce the nitroxides to the nonparamagnetic hydroxylamines.³⁵ While this effect was originally considered only to be a drawback, subsequently it has been demonstrated to be a potentially powerful tool for following redox metabolism. In principle this effect could be followed both by direct EPR studies and by NMR (the latter by using the change in contrast from the change in local concentrations of the nitroxides). Extensive studies of the reduction of nitroxides and its reverse, the oxidation of hydroxylamines back to nitroxides by various cellular systems, have shown that these metabolic rates can be very sensitive indicators of the presence of profound hypoxia, with the principal changes in the rate of metabolism occurring at $pO_2 < 1$ torr.³⁶ This approach is similar to NMR measurements of phosphorus metabolites (e.g. Pi/ATP ratio) and lactic acid production, both of which appear to change especially when the pO_2 becomes very low. To date, however, data are lacking on the correlation between these changes as followed by NMR and the actual concentration of oxygen.

The nonoxygen dependent metabolism of nitroxides should also be a very useful parameter for evaluating redox metabolism *in vivo*. The reduction of the nitroxides to the hydroxylamines occurs primarily through reduction by the mitochondria, with the reducing equivalents coming from approximately the level of ubiquinone. Therefore the rate of reduction of nitroxides can provide a useful measure of this activity that may not be obtainable by other means *in vivo*. Redox processes at different sites can be followed selectively by the use of nitroxides whose physical or chemical properties (e.g. solubility, charge, reactivity of side groups) result in their selective localization.

Recent studies illustrate the potential for using the metabolism of nitroxides as a means of investigating redox metabolism *in vivo*. These uses may be extended to the study of other biophysical parameters which can be reflected in the EPR spectra of nitroxides. There are many regions of interest such as tumors which fall within the sensitive depth for 1 GHz EPR and there are also some techniques in which an insertable probe can be used to probe depths up to several cm with this frequency.⁴ These approaches may be especially useful in studies of the skin since the depth of penetration of microwaves is sufficient to cover the region of interest using a surface probe. We describe some of these studies in skin as an indication of what might be obtained in other systems as well.

Nitroxides have been applied topically and their diffusion into skin and their metabolism deduced from temporal changes of 1D EPR spectra in the presence of a field gradient orthogonal to the skin surface. Both the rate and spatial distribution of the physiological processes involved in the metabolism of nitroxides or nitroxide-labeled compounds can be studied. Fuchs et al.³⁷ studied diffusion of several nitroxides into skin biopsies of hairless mice and found that penetration of lipophilic nitroxides is much faster than penetration of more hydrophilic nitroxides. They also studied percutaneous absorption and distribution of a nitroxide-labeled drug (estradiol) and a local anesthetic (procaine) finding that the former readily penetrates into deep skin layers while the latter does not, even in the presence of a penetration enhancer, such as dimethyl sulfoxide. Using spectral spatial imaging and analysis of spectral features, the same authors showed spatially resolved (surface, epidermis, dermis) partitioning of the nitroxide di-*t*-butyl nitroxide (DTNB) between polar and apolar regions (Figure 2), as well as the spatial distribution of thiol groups by studying the diffusion of proxylmaleimide, which chemically reacts with thiol groups.

The study of Gabrijelcic et al.³⁸ illustrates the capability of studying potential applications of liposomes as drug carriers for topical treatment of skin disorders. They found that entrapment in liposomes promotes the penetration of otherwise impenetrable, charged nitroxides into pig skin and that the size and phospholipid composition of liposomes significantly influences their efficiency. Combining these results with the study of reduction of free nitroxides, the loss of integrity of liposomes in different layers of the skin was assessed.³⁹ The physiological information obtained by EPR in these studies cannot be obtained by other imaging modalities (MRI, ultrasound), with the same spatial resolution (well below 100 μm). Although these experiments were performed at 9 GHz and used tissue slices, there are no apparent obstacles for the use of these techniques in living animals (or humans) using lower frequency spectrometers.

Another area of overlapping interest for both EPR and MRI is the study of redox metabolism of ischemia/reperfusion injury of the heart. Free radicals derived from oxygen are believed to be involved in reperfusion injury of cardiac tissue, but current techniques do not permit their direct observation. However, generation of free radicals and underlying molecular mechanisms can be studied indirectly by spin-trapping, and the potential of this approach has been investigated in isolated perfused hearts⁴⁰ using nitroxides which resemble the molecular structure of the most commonly used spin-trapping molecules. Zweier & Kuppusamy^{11,28} studied the kinetics of nitroxide uptake from perfusate and their subsequent reduction upon induction of ischemia. The average oxygen concentration was simultaneously determined from measurements of linewidth. By including spectral spatial imaging in the experimental protocol and synchronizing acquisition with the heart beat these experiments could provide valuable data.

There is also a wide range of biophysical parameters that can be studied by EPR since nitroxide spectra are sensitive, in addition to $p\text{O}_2$, to viscosity, polarity, membrane order and fluidity, pH, redox processes, and other metabolic properties. Some of these parameters are not amenable to study by other means and could be very useful for understanding changes detected by NMR techniques.

4 MEASUREMENT OF THE VIABILITY OF CELLS, ESPECIALLY BY EPR MICROSCOPY

EPR has the capability of measuring the viability of cells in an accurate, nonperturbing, and repeatable manner, under appropriate circumstances.⁴¹ This essentially unique capability is based on the use of nitroxides in combination with the presence of significant concentrations of charged, paramagnetic metal ions. Under these circumstances the EPR signal from the nitroxides is observable only where the nitroxide is not in close proximity to the metal ion. This occurs inside viable cells; when the cells lose their viability the EPR signal from those cells is suppressed. This measure of viability, which reflects the function of the membrane, appears to correlate well with other measures of viability.⁴¹

This approach is most suitable at higher frequencies (e.g. 9 GHz) where there is maximum sensitivity; at such frequencies this approach can be used for microscopic imaging with resolution of the order of cell dimensions or less.

This approach has been used successfully in spheroids, which are an important and frequently used *in vitro* model of solid tumors.⁴² The authors have demonstrated that noninvasive assessment of spatial distribution of viable and necrotic regions of spheroids can be done using 2D EPRI microscopy (Figure 3). They used a water soluble, cell permeable nitroxide (¹⁵N substituted, perdeuterated Tempone) and a paramagnetic broadening agent (chromium oxalate), which is excluded from viable cells, but enters dead cells thus leaving observable only nitroxide signals from living cells. Using a magnetic field gradient of 1 T m⁻¹, a linear resolution of 10–20 μm was obtained; this is quite comparable to that obtained in a similar MRI study.⁴³ The method was used to resolve microscopic areas of necrosis in spheroids at different stages of their growth. The same approach has also been used to study the cytotoxicity of an antitumor drug (Adriamycin). The advantages of this approach

Figure 2 Penetration of DNTB into mouse skin as monitored by EPR imaging at 9 GHz. Punch biopsy samples were pretreated with *N*-ethylmaleimide prior to topical application of DNTB. Left: 2D spectral spatial images of the time dependent changes of the distribution of DNTB: (a), 5 min; (b) 15 min; (c) 45 min. Right: EPR spectra of DNTB (2nd harmonics) in different layers of the skin: (a) epidermal surface; (b) epidermis; (c) dermis. A splitting of the high-field resonance line, h-1, into two peaks indicates distribution of DNTB between apolar (h-1a) and polar (h-1p) microenvironments within the epidermis and dermis. include that it can be applied to single spheroids and that the same spheroid can be studied repeatedly over periods of several weeks.⁴¹

This technique could potentially be used *in vivo*, although this would necessarily involve lower resolution because of the lower frequency that is needed for *in vivo* EPR, and a method would need to be developed for achieving locally high concentrations of a suitable paramagnetic metal ion.

Another potential approach to the use of EPR to measure viability *in vivo* was demonstrated by Berliner et al.⁴⁴ in the first reported EPR image of a living animal. Using an EPR

spectrometer operating at 1.5 GHz and a loop-gap resonator they obtained images of a melanoma which was implanted into the tail of a mouse, using serial intravenous (i.v.) injections of a nitroxide (CTPO; 3-carbamoyl-2,2,5,5-tetramethyl- pyrroline-1-oxyl) as the imaging agent. Although reconstructed from only four projections, the resulting 2D image of the tumor showed distinguishable necrotic and viable areas. Additional studies are needed to determine if the distribution plus metabolism of nitroxides can provide a reproducible means of distinguishing between viable and nonviable regions. If so, the resolution obtainable when imaging at 1 GHz may be sufficient to provide

Figure 3 Two-dimensional EPRI microscopy (gray scale and surface plots) of cell viability in spheroids at different stages of growth: (a) and (b) = 12 days; (c) and (d) = 3 weeks; (e) and (f) = 5 weeks, or diameter of 0.58, 0.99 and 1.49 mm. The intensity of the image corresponds to the amount of viable cells in different regions. Note that the thickness of the viable rim remains the same regardless of the size of the spheroid (bars are approximately 0.2 mm). For each image 64 projections were collected with a magnetic field gradient of 0.9 T m^{-1} . (Reproduced by permission of Macmillan Press from J. W. Dobrucki, F. Demsar, T. Walczak, R. K. Woods, G. Bacic, and H. M. Swartz, *Br. J. Cancer*, 1990, **61**, 221)

very useful information, especially in connection with studies of metabolism by NMR spectroscopy.

5 MEASUREMENT OF THE CONCENTRATION AND DISTRIBUTION OF CONTRAST AGENTS, ESPECIALLY IN VIVO

5.1 Nitroxides

The main interest in studying nitroxides as potential MRI contrast agents arises from the concept of metabolically responsive contrast agents.^{34,45} Namely, if the administered paramagnetic contrast agent can undergo reduction or oxidation to a nonparamagnetic product, then it may be possible to obtain a set of images where the contrast reflects regions with different redox metabolism. The productive use of nitroxides as metabolically responsive contrast agents for MRI requires knowledge of at least three elements: their metabolic responsiveness; their effectiveness as relaxation enhancers; and their pharmacological properties.

5.1.1 Metabolic Responsiveness of Nitroxides

In vitro EPR studies of mammalian cells in suspensions⁴⁶ showed that virtually all nitroxides undergo metabolism to a nonparamagnetic state under appropriate conditions and that the rate of reduction is primarily affected by the concentration of oxygen. Susceptibility to reduction varies by a factor of more than 100 between different nitroxides, with the principal factors being whether the nitroxide readily enters the cells and the structure of the ring to which the nitroxide group is attached (nitroxides based on five membered rings are generally more resistant to reduction than nitroxides based on the six-membered piperidine ring). The mechanism of metabolic reduction in vivo has been studied only to a limited extent^{29,47–49} but it seems that the relationship between the structure of the nitroxides and their susceptibility to bio-reduction is similar to that observed in vitro systems. It has also been shown that cells can oxidize hydroxylamines back to paramagnetic nitroxides,⁵⁰ which raises the possibility of administering hydroxylamines and obtaining differential amounts of contrast in direct proportion to the tissue pO_2 .

5.1.2 Relaxivity of Nitroxides

The ability of nitroxides to affect the relaxation times of protons (i.e. relaxivity) is an order of magnitude lower than that of metal ions. The nitroxides are spin- $\frac{1}{2}$ systems with a single unpaired electron, which is a disadvantage when compared with metal ions (e.g. Mn or Gd) that have several unpaired electrons. A second disadvantage is that nitroxides do not bind water tightly, in contrast to the metal ions and their complexes, so that relaxation occurs via relatively inefficient outer sphere mechanisms.⁵¹ However, the relaxivity of nitroxides can be improved by binding them to macromolecules which changes their rotational mobility and the correlation times of the interaction of the unpaired electron and the proton. In order to optimize such an approach, two major points should be considered: the possibility of binding multiple nitroxides to

macromolecules and the degree of the immobilization of the nitroxide groups. EPR plays a key role in designing such types of contrast agents since both the number of nitroxides per macromolecule and their molecular dynamics can be determined directly from EPR spectra. Several nitroxide-macromolecule (serum albumin, polysaccharide, fatty acids) complexes have been investigated by EPR, and their relaxivity and in vivo distribution have been determined by NMR.^{51–55} In addition to increasing relaxivity, binding of nitroxides to certain vector molecules such as arabinogalactans, which are specifically taken up by hepatocytes, increases organ selective delivery while retaining metabolic responsiveness.⁵⁵

5.1.3 Pharmacological Studies of Nitroxides

The nitroxide groups themselves appear to play a relatively minor role in the distribution of the nitroxides, which is usually determined by the other parts of the molecule based on the usual factors such as size, charge, and lipophilicity. The in vivo kinetics appear to be highly complex, depending upon the type of nitroxide, amount of reduction that can occur in the blood, specific accumulation in particular organs, cellular uptake and intracellular reduction rates, and clearance mechanisms. Figure 4(a) and (b) illustrate an in vivo EPR spectroscopy experiment in which patterns of distribution and reduction of three nitroxides were followed.⁴⁷ A surface detector was placed over the region of interest to localize the spectra. The different behavior of the three nitroxides [Figure 4(a)] reflects differences in the rate of membrane permeation and bio-reduction and is consistent with results from in vitro studies. These experiments also demonstrated the presence of ascorbate in the bladder. Reduction by ascorbate in the bladder caused the decay of the EPR signal of Cat₁ [Figure 4(b)]. Subsequent in vivo EPR spectroscopic studies further analyzed the pharmacology of nitroxides in these and other organs such as brain and lungs.^{29,48,49} Although these experiments were designed to study nitroxide metabolism and their potential use as a metabolically sensitive contrast agent for MRI or EPR imaging, the same technique, combined with the use of spin-labeled analogs of drugs, could also be used for detailed pharmacokinetic studies of a wide range of drugs taking advantage of the high specificity and sensitivity of EPR spectroscopy.

Low-frequency EPRI (operating frequencies 1.2 GHz to 280 MHz) has also been used in pharmacological studies.^{56,57} While demonstrating that potentially both whole body distribution and pharmacokinetics can be simultaneously studied, these papers also outlined some of the principal problems facing in vivo EPRI. As already mentioned, the major problem arises from the fact that the imaging substance (nitroxide) has to be introduced externally. Toxicity considerations limit the maximum amount to be administered and although in vivo EPR spectrometers can in principle detect very low concentrations of nitroxides ($1\text{--}10\ \mu\text{mol kg}^{-1}$), imaging requires at least 100-fold higher concentrations and even then the resulting image may have a rather poor signal/noise ratio. The inability of in vivo EPRI to utilize pulsed, slice selected imaging procedures results in a long imaging time and/or a small number of projections. The acquisition time for 2D images is 2–10 min which is acceptable, but results in superposition of different planes so that it can be difficult to interpret images on an ana-

Figure 4 In vivo EPR spectroscopy. (a) and (b) Pharmacokinetics of nitroxides. (a) Decrease of the intensities of the EPR signals of nitroxides from the liver region of mice following the i.v. injection of three different nitroxides: Tempone (4-oxo-2,2,6,6-tetramethylpiperidine-1-oxyl), Cat₁ (4-trimethylammonium-2,2,6,6-tetramethylpiperidine-1-oxyl), and PCA (3-carboxy-2,2,5,5-tetramethylpyrroline-1-oxyl) at doses 0.10–0.15 mmol kg⁻¹ body wt. The signals of all nitroxides are normalized to the signal intensity at the termination of injection. The temperature of the mice was maintained at 37 °C. The inset shows the in vivo spectrum of PCA obtained 5 min after injection. (b) The EPR intensities of Cat₁ from the bladder region under the same experimental conditions. The decrease of the signal from the vascular pool, measured by the placement of the surface probe over regions without localized uptake, is also shown (solid and open circles indicate points from two different experiments). (c) and (d) Studies of the status of liposomes. Changes of the intensity of the EPR signal of a nitroxide from the liver region of a mouse following the i.v. injection of Cat₁ encapsulated in dipalmitoyl phosphatidylcholine/DPPG liposomes. The injected dose was 0.03 mmol kg⁻¹. (c) Changes of the signal intensity vs. time after injection. The temperature of the mouse was maintained at 30 °C, i.e. below the phase transition point of liposomes. The inset is a typical spectrum obtained 30 min after injection. The broken line shows a typical blood clearance curve for these liposomes. (d) Changes of the signal intensity vs. temperature of the mouse. Heating of the mouse by flowing warm air (1 °C min⁻¹) was started 30 min after injection of the liposomes. (Reproduced by permission of Academic Press from G. Bacic, M. J. Nilges, R. L. Magin, T. Walczak, and H. M. Swartz, *Magn. Reson. Med.*, 1989, **10**, 266)

tomical basis. True zeugmatographic 3D images require 20–80 min, during which a concentration of nitroxide in a selected region has to be maintained as constant. Reported inplane resolution for rat head at 780 MHz was 0.5 mm with an effective slice thickness of 1.5 mm. Resolution can be improved by using larger field gradients, but this would, besides being technically demanding, further reduce the S/N ratio of the image. In addition, all resonators currently used have a nonhomogeneous rf field distribution, particularly along the axial direction, which further complicates accurate image reconstruction. Use of larger resonators can alleviate this problem, but at the expense of a further reduction in sensitivity. A potential solution for many of the above mentioned problems is the development of pulsed EPRI techniques. The frequency ranges of in vivo

EPRI machines nowadays overlap with high-field MRI machines, which should make development of pulsed EPRI easier. Until then, it seems that much more reliable images of spin-labels in animals can be obtained using standard MRI⁵⁵ or proton electron double resonance imaging (see *Overhauser Effect Imaging of Free Radicals*).

5.2 Other Contrast Agents

Metal ion (e.g. Mn, Gd) complexes or aggregates (iron particles) are paramagnetic species and it would appear that their pharmacology can be directly studied using in vivo EPR in the same manner as for nitroxides. However, at the low fields,

required for in vivo EPR, their EPR spectra have some unfavorable characteristics that effectively prevent their detection in vivo. For example, the spectrum of Gd-DTPA at 9.5 GHz contains one broad line spanning 60 mT and measurements of physiological concentrations of species with such broad resonant lines are well below the sensitivity of *L*-band EPR spectrometers. Despite these limitations, a few studies demonstrate that properly designed EPR studies can substantially add to our understanding of the pharmacology of MRI contrast agents. For example, liposomes have been extensively studied as an alternative means for targeted delivery of contrast agents. Encapsulation of contrast agents within liposomes increases selective delivery, but restricts the accessibility of the tissue water to the relaxation center. It has been found that a liposome encapsulated contrast agent (Mn^{2+}) delivered to the liver remains MRI silent as long as it is confined within liposomes or Kupffer cells due to the limited exchange of water.⁵⁸ Consequently, measurements of the rates of liposome breakdown and subsequent redistribution of contrast agents are important steps in evaluating the usefulness of liposomes as carriers of contrast agents. MRI detects these processes indirectly via changes in water relaxation and the results are often difficult to interpret, but EPR can be used effectively for these measurements as illustrated in Figure 4(c) and (d).⁴⁷ The experiment took advantage of the rapid bio-reduction of the nitroxide, Cat_1 , to follow the integrity of the liposomes in the liver, because intact liposomes protect encapsulated Cat_1 from bio-reduction. When liposomes were heated to near their transition temperature, their contents began to leak out and the EPR signal decreased as the Cat_1 became reduced. The clearance from the blood of the intact liposomes could also be followed by this technique.⁵⁸ Besides the localization within the tissue, the state of the contrast agent (bound/free) also has a profound effect on relaxation enhancement. Again MRI measures this indirectly, but EPR can measure free and bound fractions directly. In an experiment similar to the one in Figure 4(c) and (d) liposomes were loaded with Mn^{2+} and liver samples at different time points were analyzed by EPR and NMR. It was determined that as long as manganese is within the Kupffer cells and is predominantly an aquoion, no substantial changes in the relaxation of the protons of water in the liver were observed. Subsequent release of manganese from Kupffer cells resulted in binding of Mn^{2+} , as detected by EPR, yielding a pronounced increase in relaxation enhancement.⁵⁸

6 CONCLUSIONS

EPR spectroscopy has capabilities which are quite complementary to those of NMR, especially for studies in vivo which involve contrast agents, and for measurements related to $p\text{O}_2$ and/or redox metabolism. The appropriate use of EPR in such studies can significantly enhance the value of the NMR studies. It is already quite clear that for *experimental* studies EPR provides data that are widely applicable and useful for NMR studies, especially the capability of measuring $p\text{O}_2$ in tissues in vivo. It is unlikely that EPR will become a widespread *clinical* tool with the very important exception that it is quite possible that in the near future it will become the method of choice for measuring $p\text{O}_2$ in tissues in vivo.

Professor of Radiology and Biochemistry, Medical College of Wisconsin, Milwaukee, WI, USA, 1970–1979; Professor of Physiology & Biophysics, Medicine, and Bioengineering, University of Illinois, Urbana-Champaign, IL, USA, 1980–1991; Professor of Radiology, Physiology, and Bioengineering Dartmouth, Hanover, NH, USA, 1991–present. Approx. 225 publications in applications of magnetic resonance to biology and medicine, measurements of pO_2 in cells and in vivo, structure and function of melanins, radiation biology, free radicals in biology and medicine, contrast agents for MRI and MRS.

Goran Bačić. b 1951. B.S., 1976, M.S., 1980, Ph.D., 1985, Physical Chemistry, University of Belgrade, YU. Postdoctoral work at University of Illinois, USA (with H.M. Swartz). Successively research associate and assistant professor at University of Belgrade. Currently visiting research professor at Dartmouth College, NH, USA. Approx. 50 publications. Research specialties: in vivo EPR and EPR imaging, proton NMR relaxation, MRI contrast agents.

In Vivo ESR Imaging of Animals

Graham R. Cherryman, Andrew D. Stevens, and Colin M. Smith

University of Leicester, Leicester, UK

1 INTRODUCTION

The first successful electron spin resonance (ESR) experiment was reported in 1945 by Zavoisky.¹ ESR spectroscopy rapidly developed into an essential tool for the analytical chemist. It is only since the mid 1960s that its value to the biologist has been established. ESR is a technique that can detect and characterize molecules (or fragments of molecules) with an unpaired electron without destroying the molecule.

The existence of radical species with unpaired electrons was first proposed in the early 1900s. The importance of radicals in biology was first recognized in the 1930s by Leonor Michaelis (1875–1949) with his work on quinones and semiquinones. Today radical species are perceived to be important in understanding the pathogenesis of common and important diseases such as cancer and ischemia/reperfusion injury in stroke and myocardial infarction. Knowing the importance of radicals in initiating tissue damage also makes them targets for therapy with appropriate antioxidant therapies aimed at reducing tissue damage resulting from the overproduction of radicals. Medical scientists are now interested in the possibility of obtaining real-time *in vivo* ESR data on intact animal and human subjects.

When a paramagnetic substance is placed in a magnetic field, the degeneracy of the energy states for the unpaired electron is lifted. Upper and lower energy states are produced and transitions occur as a result of the absorption or emission of electromagnetic (em) energy at the resonant frequency. An ESR signal is obtained as a result of the net absorption of em energy which results from the slightly greater population of the lower energy level under nonsaturating conditions. The type of radical present determines the em frequency and magnetic field strength where this absorption occurs (*g*-factor). For technical reasons the absorption spectrum is usually plotted as a first derivative. The influence of magnetic nuclei within the molecule will split the ESR signal into several components (hyperfine splitting), which in turn will help characterize the radical species present. The linewidth of the ESR spectrum is also influenced by variations in the local paramagnetic environment. ESR signals are specific for the presence of unpaired electrons and can be obtained even when the majority of molecules present are nonradicals.

Biological ESR experiments are typically conducted at microwave frequencies, on tiny body fluid and tissue samples. Specimens are often frozen to 77 K to slow down the rapid bioreduction of short-lived natural radical species. Under these

conditions ESR signals can be obtained from almost all tissues. The validity and usefulness of many of these observations remains to be determined.

In order to obtain adequate signal from larger aqueous samples and animals, ESR experiments must be conducted at a lower frequency than currently used in the laboratory so as to achieve sufficient tissue penetration or depth. Existing spectrometers may be modified to experiment on small animals or parts of an animal, e.g. a rat tail can be imaged at low microwave *L*-band frequencies, but for serious animal work and eventual human studies the ideal em frequency will lie in the radiofrequency region.

The present challenge is to develop radiofrequency ESR spectrometer design to a point where spectra and images can be obtained with suitable sensitivity on large biological specimens and to develop satisfactory methods of image creation and processing.

2 RADIOFREQUENCY ESR SPECTROMETERS AND IMAGERS

These are still at an early stage of development.^{2,3} The essential components are (i) an rf bridge with transmitter and receiver circuitry, (ii) a resonator or surface coil, (iii) a magnet assembly and power supply for producing B_0 , (iv) magnets and power supplies for producing G_x , G_y , and G_z , and (v) a host computer(s) for control, data accumulation and image processing.

Continuous wave (CW) irradiation is normally used, in contrast to the pulse techniques used in MRI, because T_2 values are normally very short (about 10^{-9} – 10^{-7} s) and the bandwidth is very broad (about 90 MHz for nitroxides). The frequency must be low enough to give complete tissue penetration without a prohibitive loss of sensitivity. The best compromise between these factors is difficult to predict. Models for tissue absorption have to be adapted to account for resonator geometry and the precise relationship between sensitivity and frequency is still a matter for conjecture. For human studies, 250 MHz is probably the upper limit.⁴ Our 250 MHz and 300 MHz rf bridges use phase-locked crystal oscillator sources which have better spectral purity than the voltage controlled oscillators normally used.^{5,6} Various systems can be incorporated into the transmitter and receiver circuitry to reduce instrumental and motional artifacts and we have designed automatic rf coupling, resonator tuning and rf phase controls for this.^{5,7}

Resonators with moderately good quality factors (Q), the most advantageous B -field characteristics and the least disadvantageous E -field geometries have to be used. Loop-gaps appear to be the most suitable. We have constructed a range of multigap, single loop and multiloop, multigap resonators up to 0.4 m in diameter.⁸ Figure 1 shows a section through a double split-ring type loop-gap which we use for whole body studies of rats and which can also be used as a surface coil for larger specimens.

B_0 is usually produced using air-cored Helmholtz coils, and is swept through the resonance position. A field of only 8.9 mT is required at 250 MHz for resonance at 'free spin' ($g = 2.0023$). The field is modulated using additional coils. Subsequent phase-sensitive detection at the modulation frequency

Figure 1 Schematic cross section of the 250 MHz double split-ring resonator. The inner radius (r_o) is 27.5 mm. The resonator is tuned by rotating the inner split ring (changing α) and by use of the servo driven tuning plates

produces a first derivative signal. Because of the large signal bandwidth, much larger field gradients than used for MRI are necessary, which can present an engineering problem with large samples. G_z is normally produced by an oil or water cooled Maxwell pair, G_x and G_y by Anderson coils or variants.⁹ Figure 2 shows the coil arrangement for our 250 MHz imager, which can produce continuous gradients of up to 15 mT m⁻¹, sufficient to give a resolution of about 5 mm using nitroxides. A multipole magnet for producing field gradients of up to 150 mT m⁻¹ has also been described.¹⁰

A spectrometer for FT ESR spectroscopy and imaging at 300 MHz has recently been constructed, but is only suitable for spectroscopy using lithium phthalocyanine crystals in vacuo, for which the FID lasts about 4 μ s,¹¹ and imaging phantom systems comprising solvated electrons, for which the FID lasts about 9 μ s. At present the signal-to-noise ratio does not appear to be better than can be obtained using CW EPR, but this is bound to improve as the technology is developed. In addition, biologically useful spin probes suited to this technique will undoubtedly be produced.

3 IMAGE RECONSTRUCTION FROM ESR SPECTRA

An ESR lineshape of a chemical species with unpaired electrons (free radical), is a function, $z(B)$, which relates ESR activity (a measure of spin density) to magnetic field and is independent of spatial position. If a constant field gradient is applied in the spectrometer, then the local magnetic field experienced in a spatial distribution of free radicals will depend upon their positions, and the measured ESR spectrum will be the mathematical convolution of the ESR lineshape of the system (the spectrum when no field gradient is applied) and the

projection $p(r, \theta)$ of the spatial distribution function $F(x, y)$ ^{12,13} (here we show results for the two-dimensional case) along the ray at angle θ defining the field gradient. In other words, the spatial extent of the free radicals causes ESR spectra to be broadened in the presence of a field gradient. If the spatial distribution is approximated on a finite grid by an array F_{ij} , then:

$$p(r, \theta) = \sum_{ij} F_{ij} \delta_{r, (x_i \cos \theta + y_j \sin \theta)} \quad (1)$$

where $\delta_{i,j} = 1$ only if $i=j$ and 0 otherwise. If units are chosen so that the field gradient has unit magnitude and the spatial origin corresponds to the middle of the magnetic field scan

Figure 2 The arrangement of magnet coils in the 250 MHz imager, viewed from above and also from the side along the y axis. The B_0 and modulation coils (mod) are not shown in the top view for the sake of clarity

range, the ESR spectrum measured for nonzero field gradient is:

$$\begin{aligned} d(B, \theta) &= \sum_i p(r_i, \theta) z(B - r_i) \\ &= \sum_i \left[\sum_{kl} F_{kl} \delta_{r_i}(x_k \cos \theta + y_l \sin \theta) \right] z(B - r_i) \\ &= \sum_{kl} F_{kl} z(B - x_k \cos \theta - y_l \sin \theta) \end{aligned} \quad (2)$$

We actually measure the first derivative spectra and integrate to form the functions $z(B)$ and $d(B, \theta)$. The first derivative spectra may be used directly but better results are obtained using $z(B)$ and $d(B, \theta)$.

In principle, the projection of the spatial distribution may be recovered exactly by deconvolution, i.e. dividing the Fourier transform of the ESR spectrum with nonzero field gradient by that of the lineshape, entry by entry, and inverse Fourier transforming the result. With a complete (infinite) set of projections, the free radical spatial distribution may be found using the convoluted back-projection formula for the inverse Radon transform and an acceptable reconstruction may be found using a large, finite set.¹² The field gradients are chosen to have the same magnitude along uniformly distributed projection angles θ between 0 and 180°. Although some workers use the Fourier reconstruction formula for the inverse of the Radon transform because it is much quicker computationally, we prefer the convoluted back-projection formula because it gives clearer reconstructions.

In practice, deconvolution is numerically unstable and a filter must be used to neglect or modify¹⁴ the Fourier coefficients that are polluted by noise. Also, having a small number of projections introduces ripple artifacts into the reconstruction whose magnitude depends inversely on the projection number. With in vivo experiments time considerations dictate that our spectra are very noisy and sometimes we must be satisfied with only 16 projections. We have therefore developed an indirect reconstruction method that avoids the numerical instability and which does not admit ripples.¹⁵ From a given spatial distribution of free radicals, one may calculate a set of ESR spectra. Starting from a simple guess and iterating, the spatial distribution, whose projections broaden the lineshape to the ESR spectra measured in a field gradient, can be found by minimizing the mean squared error between observed and calculated spectra. If the observed spectrum at angle θ is denoted $d(B, \theta)$ we define the mean squared error as:

$$S^2 = \frac{1}{n} \sum_{ij} \left[\sum_{kl} F_{kl} z(B_i - x_k \cos \theta_j - y_l \sin \theta_j) - d(B_i, \theta_j) \right]^2 \quad (3)$$

where n is the total number of measured data points. S^2 is minimized initially using a simple steepest descent update, which is chosen to ensure that F_{ij} are all nonnegative, using exact first derivatives and then following with a maximum entropy¹⁶ algorithm to give a reconstruction that is closely consistent with the real data without fitting the random noise. This method is much slower than the convoluted back-projection reconstruction, but it does avoid the numerical instability and does not produce the ripple artifacts. Figure 3 shows a maximum entropy reconstructed image from 16 projections of a rat using our ESR spectrometer.

4 ESR IMAGING EXPERIMENTS

In 1971 Hutchison and Mallard reported endogenous ESR signals from a live mouse using a 100 MHz ESR spectrometer.¹⁷ In 1987 Berliner et al.¹⁸ demonstrated ESR signals arising from a melanoma tumor implanted into a mouse tail and imaged at L -band, following the intravenous injection of the nitroxide spin label CTPO (2,2,5,5-tetramethyl-1-oxylpyrrolidine-3-carboxamide). Four projections were used to construct a low resolution, filtered, back-projection image, which appeared to show central necrosis within the tumor. Subsequent serial studies showed dynamic differences in spin density between different regions of the tumor.

Figure 3 Sagittal maximum entropy reconstructed 250 MHz ESR image of a rat after injection of ^{15}N PCA (2,2,5,5-tetramethyl-1-oxyl-[^{15}N]pyrrolidine- d_{15} -3-carboxylic acid) (1 mL, 16 mM). Field gradients of 15 mT m^{-1} and a power level of 80 mW were used. Data were accumulated in 7 min and corrected for signal decay due to metabolism. The resonator split rings are shown for reference. The animal was positioned with the head toward the bottom of the resonator. A variation in spin density is seen with the highest concentration in the bladder. An area of increased spin density in the abdomen is most probably due to the concentration of the spin probe in the kidneys

The same group¹⁹ then followed the in vivo pharmacokinetics of the same intravenous nitroxide (CTPO) by serial ESR spectra obtained from a rat tail inserted into a cavity resonator again operating at *L*-band. They observed that bioreduction of the nitroxide to the corresponding hydroxylamine in the plasma accounted for the bulk of signal loss rather than urinary or biliary excretion of the tracer.

A method of three-dimensional (3D) reconstruction was first proposed by Colacicchi et al. in 1988,²⁰ followed in 1989 by reports on spatial localization of signal and oximetry in mice.²¹ In 1990 Alecci et al.²² published a 3D reconstruction of the injected spin label 3-carbamoyl-2,2,5,5-tetramethyl-3-pyrrolidin-1-yloxy in the tail vein of a 300 g anesthetized rat. The solution (1 mL, 50×10^{-3} M) was injected into the caudal vein and spectra collected over the following 18 min. The images were calculated by Fourier interpolation from 32×8 field gradient orientations. The experiment was performed at 1.2 GHz. The same group published their experience with free radical pharmacokinetics in vivo.²³ In Japan, spin labeled images of a rat head were obtained at *L*-band.²⁴

With the success of *L*-band ESR imaging the move to radiofrequency became inevitable. A new generation of ESR equipment was required. Fortunately CW ESR imagers could be constructed at relatively low cost. The Leicester (UK) group published their description of a small bore 300 MHz machine.⁵

In vivo radiofrequency ESR experiments have now been published from several groups including some from Italy^{2,25} and Leicester, UK. In Leicester a much larger 250 MHz ESR imager has been built and used for in vivo imaging in the rat.^{6,7,15,26,27} A surface coil has been constructed for use with larger animal and human subjects.²⁶

5 THE FUTURE

There is sufficient evidence to suggest that in vivo spin label ESR spectroscopy and imaging at radiofrequency using nitroxide tracers works. We should expect to see in the next few years rapid development of the technique as a method of investigating intra and extracellular redox status.²⁸ Nitroxides constitute an extensive and diverse area of organic chemistry. There are already nitroxide analogs of many molecules of interest in medicine. Nitroxides with variable side chains can be used to localize within specific body compartments. When considering the development of nitroxide compounds for human use as ESR spin labels it is reassuring to note that some nitroxides, including PCA, which at one time were under development as possible paramagnetic contrast agents for MRI, showed remarkably little toxicity.²⁹⁻³¹

Other ESR spin labels will also emerge. To develop ESR imaging there is also a need to develop single line spin labels with longer T_1 and T_2 relaxation times than found at present with nitroxide compounds. This will allow the development of 'pulse' ESR equipment capable of working in a similar fashion to FT MRI. In the laboratory experiments on lithium phthalocyanine and compounds based on carbon, semiquinones and the $\text{Ph}_3\text{C}^\bullet$ radical have shown some of the necessary characteristics.

Swartz and colleagues have pioneered the use of spin labels to measure tissue oxygenation in vivo.³² Promising compounds

include lithium phthalocyanine and fusinite,³³ nitroxide-liposome systems,³⁴ carbohydrate chars³⁵ and India ink.³⁶

Will we ever be able directly to image endogenous free radicals of medical interest? This seems unlikely due to their low concentrations and ultrashort half-lives. It is possible that suitable, safe, spin traps with identifiable spin adducts will evolve and provide some useful information about the turnover of the highly reactive radicals found in the body.³⁷ These same spin trap compounds may have a therapeutic effect through trapping the reactive radicals. This possibility is likely to act as a stimulus to the development of effective spin traps.

Animal experimentation is crucial to the development of human ESR imaging. It is only by demonstrating the ability of in vivo ESR imaging to answer important clinical questions that suitable, safe, spin labels and spin traps will be developed for human use.

1 INTRODUCTION

In principle, accurate interatomic distances can be evaluated from careful analysis of specific dipolar interactions that were normally sacrificed under the condition of high power decoupling and magic angle spinning (MAS) techniques. A number of methods to recouple a single pair of dipolar interaction among homo and hetero nuclear spin pairs under the magic angle spinning condition have been proposed for determining the interatomic distances.^{1–10} These distances have been used as constraints to determine the three-dimensional (3D) structure of peptides and proteins.^{11–16} Rotational Echo DOuble Resonance (REDOR) was explored to recouple the relatively weak heteronuclear dipolar interactions under the MAS condition by applying a π pulse synchronously with the rotor period.^{8,9} Consequently, the transverse magnetization cannot be refocused completely at the end of the rotor cycle, leading to a reduction of the echo amplitude. The extent of the reduction of the echo amplitude as a function of the number of rotor periods depends on the strength of the heteronuclear dipolar interaction. This method is extensively used to determine the relatively remote interatomic distance of 2–8 Å. When a number of isolated pairs are involved in a REDOR dephasing,

the REDOR transformation could be useful in determining interatomic distances because it yields single peaks against distance axis for each heteronuclear coupling strength.^{17,18} This approach is, however, not applicable for the case where the observed nuclei in REDOR are coupled with multiple nuclei.

It turned out that determination of accurate interatomic distances (± 0.1 Å) is a prerequisite to arrive at a unique 3D structure of peptides and proteins.^{15,16} It is emphasized that the distance measurement by REDOR is the only available means to satisfy this condition among the many kinds of proposed procedures mentioned above in view of the achieved accuracy and precision. Nevertheless, it is important to bear in mind that every possible effort to achieve the distance measurement with ultimate accuracy is essential to any possible applications. This is because any measurement based on the peak-intensity is susceptible to unexpected errors, which are not easy to check. After brief survey, tips to avoid this problem will be discussed in detail.

2 THEORETICAL BACKGROUND OF THE REDOR EXPERIMENT⁸

Transverse magnetization that precesses about the static magnetic field due to the dipolar interaction under the MAS condition moves back to the same direction at every rotor period because the integration of ω_D over one rotor period is zero. Consequently, the rotational echo signals are refocused at every rotor period. When a π pulse is applied to the I nucleus (Figure 1), which is coupled with the S nucleus, in one rotor period, this pulse plays a role to invert the precession direction of the magnetization of the observed S nucleus. Consequently, the magnetization vector of the S nucleus cannot move back to the same direction after one rotor period. Therefore the amplitude of the echo intensity decreases.

The extent of the reduction of the rotational echo amplitude yields the interatomic distances. To evaluate the REDOR echo amplitude theoretically, one has to consider the average precession frequency in the presence of the π pulse at the center of the rotor period over one rotor cycle as follows:

$$\begin{aligned} \overline{\omega_D(\alpha, \beta)} &= \pm \frac{1}{\text{Tr}} \left[\int_0^{\text{Tr}/2} \omega_D dt - \int_{\text{Tr}/2}^{\text{Tr}} \omega_D dt \right] \\ &= \pm \frac{D}{\pi} \sqrt{2} \sin 2\beta \sin \alpha \end{aligned} \quad (1)$$

Figure 1 Pulse sequence and timing chart of REDOR experiment

2 NUCLEAR INTERACTIONS

where α is the azimuthal angle and β is the polar angle defined by the internuclear vector with respect to the rotor axis. Therefore, the phase angle, $\Delta\Phi(\alpha, \beta)$ for the Nc rotor cycle can be given by

$$\Delta\Phi(\alpha, \beta) = \overline{\omega_D(\alpha, \beta)} \text{NcTr} \quad (2)$$

where Tr is the rotor period. Finally, the echo amplitude can be obtained by averaging over every orientations as follows

$$S_f = \frac{1}{4\pi} \int_{\alpha} \int_{\beta} \cos[\Delta\Phi(\alpha, \beta)] d\alpha \sin\beta d\beta \quad (3)$$

Therefore, the normalized echo difference, $\Delta S/S_0$, can be given by

$$\frac{\Delta S}{S_0} = \frac{S_0 - S_f}{S_0} = 1 - S_f \quad (4)$$

Experimentally, REDOR and full echo spectra are acquired for a variety of NcTr values and the respective REDOR (S_f) and full echo (S_0) amplitudes are evaluated.

3 ROTATIONAL ECHO AMPLITUDE CALCULATED BY THE DENSITY OPERATOR APPROACH¹⁵

The REDOR echo amplitude can be evaluated more rigorously by using density matrix operators and for the REDOR experiment. The time evolution of density operator, ρ_0 , under the heteronuclear dipolar interaction during one rotor period, can be considered by taking the pulse length into account. The average Hamiltonian in the rotating frame over one rotor period can be given by

$$\begin{aligned} \overline{\mathcal{H}} &= \frac{1}{\text{Tr}} \left[\overline{\mathcal{H}_1(t)\tau} + \overline{\mathcal{H}_2(t)\tau} + \overline{\mathcal{H}_3(t)\tau} \right] \\ &= \frac{D}{4\pi} \left\{ \sin^2\beta [\sin(2\alpha + \omega_r t_w) + \sin(2\alpha - \omega_r t_w) - 2\sin 2\alpha] \right. \\ &\quad - 2\sqrt{2}\sin 2\beta \left[\sin\left(\alpha + \frac{1}{2}\omega_r t_w\right) + \sin\left(\alpha - \frac{1}{2}\omega_r t_w\right) + 2\sin 2\alpha \right] \\ &\quad - \sin^2\beta [\sin(2\alpha + \omega_r t_w) + \sin(2\alpha - \omega_r t_w)] \frac{4\omega_r^2 t_w^2}{4\omega_r^2 t_w^2 - \pi^2} \\ &\quad + \sqrt{2}\sin 2\beta \left[\sin\left(\alpha + \frac{1}{2}\omega_r t_w\right) + \sin\left(\alpha - \frac{1}{2}\omega_r t_w\right) \right] \\ &\quad \times \frac{2\omega_r^2 t_w^2}{\omega_r^2 t_w^2 - \pi^2} \left. \right\} \hat{I}_Z \hat{S}_Z \\ &+ \frac{D}{4\pi} \left\{ \sin^2\beta [\cos(2\alpha + \omega_r t_w) + \cos(2\alpha - \omega_r t_w)] \right. \\ &\quad \times \frac{2\pi\omega_r t_w}{4\omega_r^2 t_w^2 - \pi^2} \\ &\quad - \sqrt{2}\sin 2\beta \left[\cos\left(\alpha + \frac{1}{2}\omega_r t_w\right) + \cos\left(\alpha - \frac{1}{2}\omega_r t_w\right) \right] \\ &\quad \times \frac{2\pi\omega_r t_w}{\omega_r^2 t_w^2 - \pi^2} \left. \right\} \hat{I}_Z \hat{S}_Y \\ &= a\hat{I}_Z \hat{S}_Z + b\hat{I}_Z \hat{S}_Y \end{aligned} \quad (5)$$

where ω_r is the angular velocity of the rotor and t_w is the duration of π pulse. $\overline{\mathcal{H}_1(t)}$, $\overline{\mathcal{H}_2(t)}$, and $\overline{\mathcal{H}_3(t)}$ are the average Hamiltonians corresponding to the period shown in Figure 1. Pulse length, t_w , is also considered in the calculations for the analysis of the REDOR results. The density operator, ρ (Tr), at Tr after evolution under the average Hamiltonian can be calculated as

$$\rho(\text{Tr}) = \exp(-i\overline{\mathcal{H}}\text{Tr})\rho_0\exp(i\overline{\mathcal{H}}\text{Tr}) \quad (6)$$

where ρ_0 is considered to be $\hat{I}_Y$ after the contact pulse. Then finally the transverse magnetization at Tr can be given by

$$\begin{aligned} \langle \hat{I}_Y(\text{Tr}) \rangle &= \text{Tr}\{\rho(\text{Tr})\hat{I}_Y\} \\ &= \cos\left(\frac{1}{2}\sqrt{a^2 + b^2}\text{Tr}\right) \end{aligned} \quad (7)$$

Echo amplitude in the powder sample can be calculated by averaging over every orientation as follows

$$S_f = \frac{1}{4\pi} \int_{\alpha} \int_{\beta} \langle \hat{I}_Y(\text{Tr}) \rangle \sin\beta d\beta d\alpha \quad (8)$$

Therefore, the normalized echo difference, $\Delta S/S_0$, can be given by equation (4). When the length of t_w is zero, equation (7) can be simplified as follows:

$$\langle \hat{I}_Y(\text{Tr}) \rangle = \cos\left(\frac{D}{\pi}\sqrt{2}\sin 2\beta \sin \alpha \text{Tr}\right) \quad (9)$$

In this case, equation (8) is equivalent to equation (3) in the case of Nc = 1.

4 SEPARATION OF S-I DISTANCES FROM A S_m - I_n MULTIPLE SPIN SYSTEM

It should be taken into account that a spin system for a doubly labeled sample should be generally treated as a multiple spin system (S - I_n system) as shown in Figure 2(a) in which S^* is the observed nuclei and the recoupling pulse is applied to the I^* nuclei. The ideal S - I system is available only when the doubly labeled preparation is infinitely diluted with unlabeled preparation. In contrast, uniformly and singly labeled preparations are treated as S_m - I_n and S - I_n systems, respectively (Figure 2b,c), although S^* in the latter is S nuclei of natural abundance. For this reason, it is advisable to utilize a variety of isotopically doubly labeled samples in order to obtain respective interatomic distances, although it is too laborious to make so many kinds of preparations. In fact, we made six kinds of doubly labeled preparations to determine the 3D structure of the pentapeptide, Leu-enkephalin.¹⁶ In addition, it is essential to make certain that all such preparations take the same polymorphic structure, because crystalline peptides or proteins under consideration may take different kinds of polymorphs depending on condition for crystallization, pH, temperature, etc.^{15,16} The most convenient way to check this problem is to use the conformation-dependent ¹³C chemical shifts,

Figure 2 Schematic representation of multiple spin systems for (a) doubly labeled, (b) uniformly labeled and (c) singly labeled samples

which are very sensitive to the presence of such polymorphic structure.^{15,16,19}

In this connection, use of a uniformly labeled sample seems to be more attractive both for the sample preparation and also to avoid the problem of polymorphs.²⁰ This view turned out to be not always true, however, because separation of a particular $S-I$ interaction from S_m-I_n spin systems, consisting of many homo- and heteronuclear dipolar and scalar interactions, is not always as straightforward as anticipated. In practice, all of the following conditions should be taken into account to determine the accurate interatomic distances of a particular spin pair from the uniformly labeled samples. First, J coupling among the observed S nuclei should be removed to reduce the phase twist due to the coherent evolution by J coupling, when its magnitude is comparable to the dipolar coupling, as illustrated for uniformly [^{15}N , ^{13}C]-labeled ammonium L-glutamate monohydrate at $\text{NcTr} = 8$ ms (Figure 3).^{21,28} This phase twist can be removed by using a shaped pulse as a Z-filter instead of a π pulse at the center position of the REDOR evolution period.²¹ Second, the linewidths of individual signals might be broadened due to strong homonuclear dipolar interaction with neighboring S nuclei, which should be eliminated by homonuclear decoupling pulses.²² Thus, in the case of a uniformly labeled sample, combination of both homonuclear dipolar and scalar decoupling is required to simplify the S_m-I_n to $S-I_n$ spin system. Third, relatively shortened transverse relaxation times (T_2), due to residual dipolar interactions, reduce the

Figure 3 ^{13}C -REDOR and full echo spectra at $\text{NcTr} = 8$ ms for crystalline uniformly labeled ammonium [^{15}N]-L-glutamate monohydrate

transverse magnetization during the dipolar recoupling period in REDOR experiments. This makes it difficult to observe the REDOR effect for the nuclei with relatively long internuclear distances, because it is required to measure relatively long evolution times to observe slow dephasing of the REDOR signals. Fourth, REDOR factors against the dipolar evolution time should be analyzed using multiply coupled $S-I_n$ spin systems rather than an isolated two-spin system under the condition of homonuclear decoupling.^{23–26} Accordingly, the four kinds of obstacles mentioned above should be removed to determine a set of accurate interatomic distances simultaneously for a uniformly labeled sample.

Gullion et al.²⁷ proposed a θ -REDOR as an approach to determine the individual interatomic distance in a uniformly labeled sample by dividing $S-I_n$ spin system into ' n ' number of isolated $S-I$ two-spin systems. This makes the REDOR analysis simple and allows one to use the REDOR transformation to obtain the dipolar coupling frequencies of individual $S-I$ spin couplings, although this method is not always easy to apply for measurement of a relatively long interatomic distance. Alternatively, homonuclear and scalar interactions are completely removed when natural abundant ^{13}C REDOR experiments were performed.²⁸ This approach provides an excellent means to determine the interatomic distances for a number of isolated spin pairs simultaneously under condition of high resolution (Figure 2c). Further, it is emphasized that this approach is free from the problem of the above-mentioned shortened T_2 values due to homonuclear ^{13}C spin interactions. However, a multiple coupled spin system, $^{13}\text{C}-^{15}\text{N}_n$, has still to be explicitly considered, because the intermolecular dipolar interactions cannot be neglected for a small molecule. In practice, we have recently demonstrated that accurate interatomic distances can be determined by analyzing intramolecular and

intermolecular dipolar contributions based on root mean square deviation (RMSD) between the theoretically and experimentally obtained REDOR factors.²⁸

5 TIPS FOR OBTAINING ACCURATE INTERATOMIC DISTANCES BY REDOR EXPERIMENT

It is emphasized that determination of interatomic distances accurate to 0.1 Å is a prerequisite to arrive at a unique solution of the three-dimensional structure of peptides, proteins, etc. A careful evaluation of the following points are the most important steps to obtain reliable interatomic distances by the REDOR experiment, although they have not always been seriously taken into account in a number of papers so far published.

5.1 The Finite Pulse Length and Fluctuation of RF Power

This effect is experimentally observed and calculated using equation (8) as shown in Figure 4. The REDOR parameter, $\Delta S/S_0$, as measured for 20% [1-¹³C, ¹⁵N]Gly($r_{\text{CN}} = 2.48$ Å) is plotted for the lengths of the ¹⁵N π pulse of 13.0 μs for the experiment and 24.6 μs (chosen to satisfy 10% rotor cycle) as a function of NcTr with the calculated lines using the π pulse

Figure 4 ¹³C REDOR and full echo spectra of [1-¹³C, ¹⁵N]glycine as recorded by the rotor frequency of 4000 Hz and NcTr of 4 ms (a) and plots of the $\Delta S/S_0$ vs. NcTr (b). Solid and open circles denote the experimental points recorded using a ¹⁵N π -pulse of 13.0 and 24.6 μs , respectively. Solid, broken and dotted lines are calculated using the π -pulses of δ , 13.0 and 24.6 μs , respectively, together with the C–N interatomic distance of 2.48 Å¹⁵

length and finite lengths (13.0 and 24.6 μs) of the π pulse. It turns out, however, that the finite length of the ¹⁵N π pulse does not significantly affect the REDOR effect provided that the pulse length is less than 10% of the rotor cycle at the rotor frequency of 4000 Hz. This effect, however, should be seriously taken into account if fast MAS, e.g., 40 kHz is used.

For most spectrometers, it is difficult to be free from fluctuations of RF power during the acquisition of REDOR experiments. It is, therefore, critical that RF power be stabilized. If not, the π pulse will vary in length. Consequently, the REDOR factor is greatly decreased to yield relatively longer interatomic distances. Compensation of instability of such RF power, e.g., by approximate pulse sequence is, therefore, necessary to be free from long term fluctuations of amplifiers. xy-4 and xy-8 pulse sequences have been developed for this purpose. The xy-8 pulse is known to be the best sequence to compensate for the fluctuation of the RF power.²⁹

5.2 Contribution from Natural Abundance Nuclei

Since the early stages of the REDOR experiment, contributions from natural abundance nuclei have been seriously considered as a major source of error in the distance measurement.³⁰ It appears that the observed dipolar interaction can be modified by the presence of such neighboring naturally abundant nuclei. This effect was originally taken into account by simply calculating the $\Delta S/S_0$ value for two isolated pairs and adding proportionally to the natural abundant fraction.³⁰ Careful analysis of the three-spin system, however, indicates that this sort of simple addition of the fraction of the two-spin system may result in a serious overestimate of the natural abundance effect, to yield shorter distances.²³ The most accurate way to consider the natural abundance effect is, therefore, to treat the whole spin system as a three-spin system by taking into account the neighboring carbons in addition to the labeled pair. In practice, contributions from naturally abundant nuclei can be ignored for ¹³C REDOR but not for ¹⁵N REDOR, because the proportion of naturally abundant ¹³C nuclei is much higher than that of the ¹⁵N nuclei.²³

5.3 Sample Dilution

¹³C, ¹⁵N-doubly labeled samples are usually used in the REDOR experiment to determine the interatomic distances between the labeled nuclei. More importantly, the dipolar interaction with the labeled ¹⁵N nuclei for the neighboring molecules should be taken into account as an additional factor to contribute to the dipolar interaction of the observed pair under consideration. This contribution could be serious when the observed distance is quite remote, because there are many contributions from nearby nuclei. This effect can be completely removed by diluting the labeled sample with a sample of naturally abundant molecules.²³ The sensitivity of the signals, however, has to be sacrificed if one wants to remove the effect completely as the sample must be diluted to 1/49 so that the signal intensity is reduced by a factor roughly 0.02.¹¹ Instead, it is advised to evaluate the REDOR factors at the infinitely diluted condition by extrapolating the data by stepwise dilution of the sample (i.e., 60%, 30%, etc.) without losing sensitivity, because a linear relationship between the REDOR factor and the dilution is ascertained by a theoretical consideration.²³ Alternatively, the observed plots of $\Delta S/S_0$ values against the

corresponding NcTr values for the sample without dilution can be fitted by a theoretical curve obtained from the dipolar interactions among three-spin systems, although the accuracy is not always improved to the level of the dilution experiment.

5.4 T_2 Effect

The transverse magnetization of the REDOR experiment decays as a function of the ^1H decoupling field.^{31,32} Under appropriate conditions, molecular motion may interfere with dipolar decoupling. This occurs when molecular motion, if any, exists when the motional frequency is of the same order of magnitude as the decoupling field, and hence the transverse relaxation times (T_2) are significantly shortened. In fact, it was found that the T_2 values of the carbonyl carbons in crystalline Leu-enkephalin are relatively short because of the presence of backbone motion.³³ This is a serious problem for the REDOR experiment, especially for the long distance pairs, because the S/N ratio is significantly deteriorated. In this case, it is required to measure the ^{13}C REDOR signal under a sufficiently strong decoupling field to elongate the transverse relaxation times. It is also useful to perform measurements at low temperature so as to reduce the motional frequency. Note, however, that crystalline phase transitions might be associated together with the freezing of the solvent molecules. This effect has been observed in a variety of enkephalin samples.^{34,35}

5.5 RF Inhomogeneity and Confinement of the Sample within RF Coil

In the commercial spectrometer, the rotor is designed to allow the sample volume to be as large as possible in order to gain better sensitivity. Obviously, this arrangement causes H_1 inhomogeneity, which results in a broad distribution of the lengths of the 90° pulses. This problem is serious for the REDOR experiment in which a number of π pulses are applied. As a result, the pulse error can accumulate during the acquisition to give serious error in the measurements of internuclear distances. Particularly, the samples located at the top or bottom part of the sample rotor feel quite a weak RF field. This causes a great reduction of the REDOR factor for a sample that is filled all the way along the sample rotor.¹⁵ This effect should be seriously taken into account prior to experiments with a commercial spectrometer. It is, therefore, strongly recommended to fill the sample only in the central part of the coil just like a multiple pulse experiment to be able to acquire as accurate interatomic distances as possible in the REDOR experiment.

5.6 Standard Sample

All of the considerations mentioned above are essential to achieve accurate interatomic distances. Nevertheless, it is also possible that accuracy may deteriorate even if one of the conditions is not satisfied for every possible measurement. It is therefore advisable to determine the interatomic distances from a standard sample, in order to check that all the conditions are satisfied. More preferentially, use of two standard samples for short and long distances is recommended. In practice, it is recommended to use [$1\text{-}^{13}\text{C}$, ^{15}N]glycine as the former standard sample whose C–N interatomic distance is determined as 2.48 Å by a neutron diffraction study, and to check that all the instrumental conditions of a given spectrometer are satisfied prior to every new experiment. As a second standard sample for long distance, it is recommended to use [^{13}C , ^{15}N]N-acetyl-Pro-Gly-Phe (Table 1). This crystalline peptide is very stable with relatively long T_2 values, because it does not contain solvent molecules, and the presence of two polymorphic structures is well characterized.¹⁵

6 NATURAL ABUNDANCE ^{13}C REDOR EXPERIMENT²⁸

As mentioned already, it is impossible to obtain meaningful interatomic distances from a uniformly labeled sample as far as the standard REDOR procedure is concerned. Instead, the natural abundance REDOR experiment is more preferable as a means free from both homonuclear dipolar and scalar interactions (Figure 3). This approach provides the interatomic distances for a number of isolated spin pairs simultaneously under high resolution conditions. Further, this approach is free from the problem of the shortened T_2 values due to homonuclear ^{13}C spin interactions. Figure 5 shows the REDOR and full echo spectra of natural abundance ^{13}C nuclei of singly ^{15}N labeled crystalline ammonium [^{15}N]L-glutamate monohydrate (I) at NcTr = 8 ms, in contrast to the twisted spectra from the same sample uniformly labeled (Figure 3). The assignment of peaks to the C_β , C_γ , C_α , $\text{C}=\text{O}$ and C_δ carbon nuclei, from high to low field, is also shown in Figure 5. The $\text{C}=\text{O}$ (176.6 ppm) peak was distinguished from the C_δ (179.5 ppm) peak as a peak yielding a stronger REDOR effect as shown in Figure 5. Similarly, the peak at 56.0 ppm was assigned to the C_α carbon nucleus that give the strongest REDOR effect among the three aliphatic ^{13}C peaks. In a similar manner, the peak at 30.5 ppm showed a stronger REDOR effect compared

Table 1 C–N interatomic distances (Å) determined from REDOR experiments as compared with those by X-ray diffraction and MD¹⁵

Labeled peptides	Experimental			Calculated		
	REDOR	X-Ray		Energy-minimized ^a	MD

^bRef.³⁶

^cData from Ref.²³ based on fully packed 7.5 mm rotor systems.

Figure 5 Naturally abundant ^{13}C -REDOR and full echo spectra at $\text{NcTr} = 8\text{ ms}$ with two different carrier frequencies for crystalline ammonium ^{15}N -L-glutamate monohydrate. Arrows indicate carrier frequency positions at the center of (a) $\text{C}=\text{O}$ and C_δ resonances; and (b) C_β and C_γ resonances

with that at 35.2 ppm. Thus, the peaks at 35.2 and 30.5 ppm were assigned to the C_γ and C_β carbon nuclei, respectively.

The interatomic C–N distances between ^{15}N and $^{13}\text{C}=\text{O}$, $^{13}\text{C}_\alpha$, $^{13}\text{C}_\beta$, $^{13}\text{C}_\gamma$, and $^{13}\text{C}_\delta$ carbon nuclei were determined with accuracy of 0.15 Å, after experimental conditions were carefully optimized. ^{13}C -REDOR factors for a three-spin system, $(\Delta S/S_0)_{\text{CNIN}_2}$, and the sum of two isolated two-spin systems, $(\Delta S/S_0)^* = (\Delta S/S_0)_{\text{CN}_1} + (\Delta S/S_0)_{\text{CN}_2}$, were further evaluated by the REDOR measurements on isotopically diluted I in a controlled manner. Subsequently, the intramolecular and intermolecular C–N distances were separated by searching the minimum in the contour map of the root mean square deviation (RMSD) between the theoretically and experimentally obtained $(\Delta S/S_0)^*$ values against two interatomic distances, $r_{\text{C-N}_1}$ and $r_{\text{C-N}_2}$. When the intramolecular C–N distance ($r_{\text{C-N}_1}$) of the particular carbon nucleus is substantially shorter than the intermolecular distance ($r_{\text{C-N}_2}$), C–N distances between the molecule in question and the nearest neighboring molecules can also be obtained, although accuracy is inevitably deteriorated. On the other hand, it was difficult to determine the interatomic distances in the same molecule

when the intermolecular dipolar contribution is larger than the intramolecular one as in the case of the C_δ carbon nucleus.

7 ACCURACY LIMIT FOR REDOR STRUCTURE OF PEPTIDE AND PROTEINS

Naito et al.¹⁵ systematically applied this technique to elucidate the three-dimensional structure of *N*-acetyl-Pro-Gly-Phe. They proposed that the carbonyl carbon of the (*i*-1)th residue and the amino nitrogen of the (*i*+1)th residue should be labeled with ^{13}C and ^{15}N , respectively. Namely, $[1-^{13}\text{C}]\text{N-acetyl-Pro-}^{15}\text{N[Gly-Phe(I)]}$, $\text{N-acetyl-}[1-^{13}\text{C}]\text{Pro-Gly-}^{15}\text{N[Phe(II)]}$ and $[1-^{13}\text{C}]\text{N-acetyl-Pro-Gly-}^{15}\text{N[Phe(III)]}$ were synthesized and the resulting distances were determined to be 3.24 ± 0.05 , 3.43 ± 0.05 , and 4.07 ± 0.05 Å respectively, utilizing the REDOR factor obtained for the infinitely diluted state to prevent errors from the contributions of the neighboring labeled nuclei. No correction from the contribution of the naturally abundant nuclei turned out to be necessary. Surprisingly, these distances do not agree well with the values obtained from an X-ray diffraction study available when the initial part of this experiment was performed, showing the maximum discrepancy between them to be 0.5 Å.³⁶ This value seems to be much larger than the expected error as estimated from the precision of the REDOR experiment (± 0.05 Å). The reason why the discrepancy is unexpectedly larger was explained by the fact that the crystal (orthorhombic) used for the REDOR experiments is different from that used in the X-ray diffraction study (monoclinic). To check the accuracy of the REDOR experiment, an X-ray diffraction study was performed on the same crystals used for the REDOR experiment. It was found that the distances from the new crystalline polymorph (orthorhombic) agree well between REDOR and X-ray diffraction, within an accuracy of 0.05 Å as shown in Table 1.

Conformational maps based on the possible combinations of the torsion angles of the Pro and Gly residues are calculated on the basis of the distance constraints thus obtained. Further, the difference of the chemical shifts between the C_β and C_γ carbons of the Pro residues $\Delta\beta\gamma$ was used as a constraint to determine the ψ value (-13°).³⁷ The ϕ angle of the Pro residue is in many instances restricted to -75° which shows the minimum energy in the residue. Therefore, the torsion angles of the Pro residue are uniquely determined to be (-75° , -28°). Using these torsion angles, conformational maps were again calculated. Finally two pairs of torsion angles were selected as (-112° , 48°) and (-112° , -48°). Minimization by a molecular mechanics calculation yielded the structure of the β -turn I structure, as shown in Figure 6(a). It is found that the three-dimensional structure of this peptide is well reproduced by a molecular dynamics simulation by taking into account all of the intermolecular interactions in the crystals, although a molecular dynamics calculation treating *single* molecular system does not always yield a correct picture as illustrated in Figure 6(b), unless otherwise all the molecules in a unit cell are correctly taken into account.^{15,38}

Elucidation of the three dimensional structure of an opioid peptide Leu-enkephalin crystal, Tyr-Gly-Gly-Phe-Leu grown from MeOH/ H_2O mixed solvent was performed by the REDOR method alone.¹⁶ This seems to be an additional challenge for this technique to reveal the three-dimensional structure of more complicated systems. Six differently labeled

Figure 6 Optimized conformation of *N*-acetyl-Pro-Gly-Phe as obtained by the minimization of energy from the initial form as deduced from the REDOR experiment (a) and a snapshot of the conformation deduced by MD simulation in vacuo (at 100 K) (b)¹⁵

Leu-enkephaline molecules were synthesized and the resulting interatomic distances (Figure 7a) are accurately determined. It turns out, however, that an extremely careful experiment is required to avoid unexpected crystalline conversion among polymorphs either by dehydration from a tightly sealed rotor or a phase transition occurring at ambient temperature. In

principle, pressure under MAS may shift a temperature of phase transition to some extent, because centrifugal force is proportional to the square of the spinning frequency. No significant effect, however, has been noted so far as a sample is spun at relatively low frequency such as 2–4 kHz but care might be taken when rotor is spun at a frequency one order of magnitude high as in 40 kHz.

This may be the reason why final refinement of X-ray diffraction data was abandoned in spite of the pioneering X-ray diffraction data as to the similarity of the tertiary structure between this opioid peptide and morphine.³⁹ Therefore, it is necessary to check whether the six differently labeled samples are all in the same crystalline polymorph by means of the ¹³C chemical shifts. Otherwise, meaningless data can be obtained without this precaution. When the distance data are converted to yield the necessary numbers of torsion angles, a unique combination of torsion angles in the corresponding conformational map is determined sequentially as shown in Figure 7(b). It is emphasized that accuracy within 0.1 Å is essential to select unique torsion angles for each amino acid residue. Namely, if the error is larger than 0.41 Å, torsion angles can no longer be selected as shown in Figure 8.

It is also important to point out that the chemical shift data can be used as additional constraints. A three dimensional structure was thus determined as shown in Figure 9. However, this structure is not the same as that previously determined

Figure 7 (a) Schematic representation between the sites of a variety of [¹³C, ¹⁵N]-doubly-labeled Leu-enkephalin dehydrates and their related torsion angles. (b) Block diagram to show how respective torsion angles are uniquely determined by the combined examinations of the conformation maps based on the distances of four-bonds apart (I, II, III and VI) and five-bonds apart (IV and V)¹⁶

Figure 8 Conformation maps for $(\Psi_{\text{Gly2}}, \omega_{\text{Gly2}})$ based on the interatomic distance of 4.55 Å with increased experimental errors: (a) ± 0.10 Å, (b) ± 0.20 Å, and (c) ± 0.41 Å¹⁶

by X-ray diffraction because one is dealing with a crystalline polymorph that is not fully explored. It is possible to figure out the molecular packing in the crystals by looking at the intermolecular dipolar contribution. Since the intermolecular dipolar contributions in I and III are larger than that of II, a β -sheet is formed as one peptide interacts with two peptides as an antiparallel β -sheet as shown in Figure 9(b).

Finally, it should be pointed out that, in order to isolate an S–I spin pair, it is essential to avoid any unnecessary errors from dipolar contributions of neighboring molecules from the overall S–I_n spin system. This is generally encountered for a variety of peptides and the aforementioned dilution procedure turned out to be not required in the case of α -helical polypeptides as far as the measurement of the interatomic distance for $^{15}\text{NH}(i) \cdots \text{O} = ^{13}\text{C}(i+4)$ is concerned.⁴⁰ This is because the interhelical dipolar contribution is found to be negligible in view of the mutual packing of α -helical chains or random mutual orientation between isotopically labeled atoms. Further, it was found that in helical peptides, due to the manner of chain packing, this kind of measurement is feasible to yield 4.5 ± 0.1 Å, without any assumptions, for a variety of transmembrane α -helical peptides in lipid bilayers to mimic a biomembrane at a temperature below liquid crystalline-gel phase transition at which rotation of such peptides about the α -helical axis turns out to be frozen, in spite of the presence

Figure 9 (a) Three-dimensional structure of Leu-enkephalin dihydrate determined uniquely by the successive application of the conformation maps as well as additional constraints of the conformation-dependent ^{13}C chemical shifts. (b) Three kinds of models for putative intermolecular packing as illustrated in the cartoons: (1) interaction through parallel β -sheet form; (2) interaction through an antiparallel β -sheet; and (3) interaction through interaction of three molecules. Solid and dotted arrows correspond with the dipolar interactions between intramolecular and intermolecular ^{13}C – ^{15}N pairs, respectively¹⁶

of rotational motions of lipid molecules, as viewed from the observation of three principal components of ^{13}C and ^{31}P chemical shift tensors.⁴¹ As is shown in this example, it is essential to ensure that molecular motion is reasonably ceased.

8 CONCLUSIONS

REDOR is one of the most powerful methods to determine accurate interatomic distances after taking into account a number of points in applying the method to a practical sample. Simultaneous measurement of interatomic distances using uniformly labeled samples can only be achieved by removing the homonuclear dipolar and scalar interactions. Alternatively, natural abundance ^{13}C REDOR measurements provide interatomic distances simultaneously free from homonuclear dipolar and scalar interactions. These accurate interatomic distances obtained from REDOR experiments can provide important information on structure and molecular packing of solid peptides and proteins.

1 INTRODUCTION

Nuclei which possess the property of spin also have an associated nuclear magnetic moment. It is the interaction between these nuclear magnetic moments and a strong applied magnetic field B_0 which forms the basis of the NMR experiment. This interaction, known as the Zeeman interaction, is always the most important spin interaction for spin- $\frac{1}{2}$ nuclei. In addition to the externally applied magnetic field, nuclei may also experience much smaller internal magnetic fields. For example, the field-induced motion of electrons generates small magnetic fields which modify the applied magnetic field and result in the phenomenon known as nuclear magnetic shielding or chemical shielding. In addition, neighboring nuclear spins may also create small magnetic fields which modify the applied magnetic field. There are two fundamental mechanisms by which one nuclear magnetic moment may interact with another: the *direct* magnetic dipole-dipole interaction and the *indirect* spin-spin interaction. The magnitude of the direct dipolar interaction is directly proportional to the inverse cube of the separation between two spins, while the indirect interaction does not depend on distance in any simple way since it is a two-stage process mediated by the intervening electrons. Because the mechanism of indirect spin-spin coupling involves electrons, this parameter depends on the detailed electronic structure of a molecule. Both the direct and indirect coupling interactions are bilinear in the nuclear spin operators (see below). In principle, the direct dipolar and indirect spin-spin interactions couple every spin of the sample with all others.

Most early NMR investigations were ^1H NMR studies, because of the relatively large magnetic moment of ^1H (hence its high inherent sensitivity to NMR detection), its large natural abundance (99.985%), and its ubiquitous presence in chemical compounds. The direct dipolar interaction has special significance in these studies since proton-proton direct dipolar interactions are largely responsible for the general appearance of ^1H NMR spectra of solid materials. Furthermore, the ^1H - ^1H dipolar interaction provided the first important application of NMR in chemistry. Specifically, Pake¹ used the ^1H - ^1H direct dipolar interaction to determine the H-H separation of water molecules in gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$): $r_{\text{H-H}} = 0.158 \text{ nm}$.

The indirect spin-spin coupling interaction was first observed as magnetic field-independent splittings in the NMR spectra of solution samples.²⁻⁴ In solution, the direct dipolar interaction averages to zero because of the rapid random tumbling motion of molecules. The first indirect spin-spin coupling constant J was reported by Proctor and Yu in 1951.² It involved the indirect spin-spin coupling between the antimony and fluorine nuclei of the SbF_6^- anion in an aqueous solution of NaSbF_6 ; $J(^{121}\text{Sb}, ^{19}\text{F}) = 1.9 \text{ kHz}$. Shortly after this report, Gutowsky and co-workers reported the observation of $J(^{31}\text{P}, ^{19}\text{F})$ in $\text{P}(\text{O})\text{Cl}_2\text{F}$ (1.2 kHz), $\text{P}(\text{O})\text{ClF}_2$ (1.1 kHz), and $\text{CH}_3(\text{O})\text{PF}_2$ (1.3 kHz).³ The first ^1H - ^1H electron-mediated spin-spin couplings were reported in the same year by Hahn and Maxwell.⁴ They studied the frequency modulation of ^1H NMR spin echoes arising from molecules with chemically nonequivalent hydrogen nuclei. For dichloroacetaldehyde (CHCl_2CHO), two distinct modulation frequencies were observed on the ^1H spin echo envelope: one corresponding to the difference in ^1H chemical shifts, and a second, much smaller frequency J which was independent of the applied magnetic field [$^3J(^1\text{H}, ^1\text{H}) = 0.7 \text{ Hz}$]. On the basis of their measurements, Hahn and Maxwell proposed that the Hamiltonian describing electron coupled spin interactions in isotropic fluids should be of the form $J_{N,N'} \mathbf{I}_N \cdot \mathbf{I}_{N'}$. However, for a pair of coupled spins residing in a molecule which is not rapidly tumbling in an isotropic fluid, Ramsey⁵ later pointed out that the energy of interaction $E_{N,N'}$ depends on the orientation of the spin pair in the applied magnetic field. In general, the energy of interaction is given by

$$E_{N,N'} = h \mathbf{I}_N \cdot \mathbf{J}_{N,N'} \cdot \mathbf{I}_{N'} + h J_{N,N'} \mathbf{I}_N \cdot \mathbf{I}_{N'} \quad (1)$$

where $\mathbf{J}_{N,N'}$ is a second rank tensor whose trace is zero and $J_{N,N'}$ is the isotropic indirect spin-spin coupling constant.

In solid samples, splittings arising from indirect spin-spin coupling were not observed until 1967.⁶ In the solid state, the magnitude of direct dipolar interactions among magnetically abundant spins, such as ^1H or ^{19}F , precluded the measurement of much smaller indirect spin-spin interactions. However, by spinning samples rapidly about an axis inclined at $54^\circ 44'$ with respect to the applied magnetic field, broadening due to anisotropic chemical shielding and direct dipolar interactions can be largely removed. Using this technique, known as magic angle spinning (MAS), Andrew et al.⁶ observed splittings due to $J(^{75}\text{As}, ^{19}\text{F})$ of 905 Hz, and $J(^{121}\text{Sb}, ^{19}\text{F})$ of 1820 Hz in the ^{19}F NMR spectra of solid KAsF_6 and KSbF_6 , respectively. From the ^{19}F NMR linewidths observed in nonspinning samples of these salts, the authors were able to conclude that the hexafluoroarsenate and hexafluoroantimonate anions are dynamically disordered. Rapid jumps of the MF_6 octahedra about their symmetry axes average *intramolecular* dipolar interactions to zero. Subsequently, VanderHart et al.⁷ studied the ^{19}F and ^{31}P NMR lineshapes of static samples of polycrystalline BaFPO_3 where the directly bonded ^{19}F and ^{31}P nuclei are coupled by both the direct dipolar and the indirect spin-spin coupling interactions. The authors indicated that with an accurate value of the ^{19}F - ^{31}P separation r_{FP} , one could calculate the contribution that the direct dipolar interaction makes to the overall ^{19}F or ^{31}P NMR lineshape and, in principle, determine the anisotropy in the indirect spin-spin coupling, a parameter which is usually inaccessible.

The objective of this article is to present an introductory discussion of how spin-spin coupling interactions are described

and how they manifest themselves in the NMR spectra of diamagnetic systems, particularly in NMR studies of solids. The discussion will focus on the indirect spin–spin coupling tensor $\mathbf{J}$, since detailed discussions of the direct dipolar interaction can be found in several textbooks on NMR.^{8–11} For pedagogical reasons, it is most convenient to focus the discussion on simple two-spin systems.

2 DIRECT DIPOLAR COUPLING

A nucleus with nonzero total spin angular momentum $\hbar\mathbf{I}$ also possesses a magnetic moment $\boldsymbol{\mu}$. The magnetic moment and angular momentum vectors are related by the magnetogyric ratio γ , a unique constant for any given isotope:

$$\boldsymbol{\mu} = \gamma\hbar\mathbf{I} \quad (2)$$

It is useful to consider the total static magnetic field emanating from a magnetic dipole. At a point P, the static field depends on the distance r and the angle θ between the magnetic dipole and P; the z component of the local field is $\gamma r^{-3}\hbar(3\cos^2\theta - 1)(\mu_0/4\pi)$. With $\theta = 0^\circ$, the local field 0.1 nm from a proton is 5.64 mT, several orders of magnitude less than the magnitude of typical external fields employed in NMR experiments.

From classical electrodynamics, the energy of interaction E between two magnetic dipoles, $\boldsymbol{\mu}_1$ and $\boldsymbol{\mu}_2$, separated by a distance r may be written as

$$E = [(\boldsymbol{\mu}_1 \cdot \boldsymbol{\mu}_2)r^{-3} - 3(\boldsymbol{\mu}_1 \cdot \mathbf{r})(\boldsymbol{\mu}_2 \cdot \mathbf{r})r^{-5}](\mu_0/4\pi) \quad (3)$$

where μ_0 is the permeability constant, $\mu_0 = 4\pi \times 10^{-7} \text{ kg m s}^{-2} \text{ A}^{-2}$. If the two dipoles $\boldsymbol{\mu}_1$ and $\boldsymbol{\mu}_2$ have the same orientation with respect to $\mathbf{r}$ then equation (3) becomes:

$$E = (\boldsymbol{\mu}_1 \cdot \boldsymbol{\mu}_2)r^{-3}(1 - 3\cos^2\theta)(\mu_0/4\pi) \quad (4)$$

where θ is the angle between the direction of the two magnetic dipoles and the vector $\mathbf{r}$ which separates them.

In NMR studies, one is generally concerned with nuclear magnetic moments. Consider two nuclei (1 and 2) separated by a distance r in a magnetic field (Figure 1). The quantum mechanical Hamiltonian describing the direct dipolar interaction, $\hat{\mathcal{H}}_{\text{DD}}$, is constructed by replacing the vectors $\boldsymbol{\mu}_1$ and $\boldsymbol{\mu}_2$ in equation (3) by their corresponding operators, $\gamma_1\hbar\hat{\mathbf{I}}_1$ and $\gamma_2\hbar\hat{\mathbf{I}}_2$:

$$\hat{\mathcal{H}}_{\text{DD}} = \gamma_1\gamma_2\hbar^2[(\hat{\mathbf{I}}_1 \cdot \hat{\mathbf{I}}_2)r^{-3} - 3(\hat{\mathbf{I}}_1 \cdot \mathbf{r})(\hat{\mathbf{I}}_2 \cdot \mathbf{r})r^{-5}](\mu_0/4\pi) \quad (5)$$

where γ_i is the magnetogyric ratio of nucleus i (in $\text{rad s}^{-1} \text{ T}^{-1}$), $\hat{\mathbf{I}}_i$ is the nuclear spin angular momentum operator, and $\mathbf{r}$ is the internuclear vector. In an NMR experiment, the direction of the magnetic moments is defined by the direction of the applied magnetic field $\mathbf{B}_0$.

If one expands the scalar products in equation (5),

$$\hat{\mathbf{I}}_1 \cdot \hat{\mathbf{I}}_2 = \hat{I}_{1x}\hat{I}_{2x} + \hat{I}_{1y}\hat{I}_{2y} + \hat{I}_{1z}\hat{I}_{2z} \quad (6)$$

$$\hat{\mathbf{I}}_1 \cdot \mathbf{r} = \hat{I}_{1x}x + \hat{I}_{1y}y + \hat{I}_{1z}z \quad (7)$$

Figure 1 Coordinate system used to describe the coupling of two spins $\hat{\mathbf{I}}_1$ and $\hat{\mathbf{I}}_2$ separated by a distance r . A strong applied magnetic field lies along the z axis

$$\hat{\mathbf{I}}_2 \cdot \mathbf{r} = \hat{I}_{2x}x + \hat{I}_{2y}y + \hat{I}_{2z}z \quad (8)$$

the direct dipolar Hamiltonian may be expanded and rewritten as

$$\begin{aligned} \hat{\mathcal{H}}_{\text{DD}} = & \gamma_1\gamma_2\hbar^2r^{-5}[\hat{I}_{1x}\hat{I}_{2x}(r^2 - 3x^2) + \hat{I}_{1y}\hat{I}_{2y}(r^2 - 3y^2) \\ & + \hat{I}_{1z}\hat{I}_{2z}(r^2 - 3z^2) - (\hat{I}_{1x}\hat{I}_{2y} + \hat{I}_{1y}\hat{I}_{2x})3xy \\ & - (\hat{I}_{1y}\hat{I}_{2z} + \hat{I}_{1z}\hat{I}_{2y})3yz - (\hat{I}_{1z}\hat{I}_{2x} + \hat{I}_{1x}\hat{I}_{2z})3zx] \\ & \times (\mu_0/4\pi) \end{aligned} \quad (9)$$

This equation can be expressed in matrix form:

$$\begin{aligned} \hat{\mathcal{H}}_{\text{DD}} = & hR \left\{ \begin{bmatrix} \hat{I}_{1x} & \hat{I}_{1y} & \hat{I}_{1z} \end{bmatrix} \right. \\ & \left. \begin{bmatrix} (r^2 - 3x^2)/r^2 & -3xy/r^2 & -3xz/r^2 \\ -3xy/r^2 & (r^2 - 3y^2)/r^2 & -3yz/r^2 \\ -3xz/r^2 & -3yz/r^2 & (r^2 - 3z^2)/r^2 \end{bmatrix} \begin{bmatrix} \hat{I}_{2x} \\ \hat{I}_{2y} \\ \hat{I}_{2z} \end{bmatrix} \right\} \end{aligned} \quad (10)$$

where R is defined as the direct dipolar coupling constant,

$$R = \gamma_1\gamma_2r^{-3}(\hbar/2\pi)(\mu_0/4\pi) \quad (11)$$

Equation (10) can be abbreviated as

$$\hat{\mathcal{H}}_{\text{DD}} = hR(\hat{\mathbf{I}}_1 \cdot \mathbf{D} \cdot \hat{\mathbf{I}}_2) \quad (12)$$

where $\mathbf{D}$ is the direct dipolar tensor.

It is easy to see that if the internuclear vector $\mathbf{r}$, lies along the z axis, then the dipolar tensor becomes diagonal:

$$\mathbf{D} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -2 \end{bmatrix} \quad (13)$$

This is the so-called principal axis system (PAS) of the dipolar tensor. Note that the principal components of the dipolar tensor

are axially symmetric, i.e. $D_{11} = D_{22}$. From equation (10) it is also obvious that the dipolar tensor is symmetric (i.e. $D_{\alpha\beta} = D_{\beta\alpha}$). Finally, it is also clear that the trace of the dipolar tensor is zero. This result indicates that the direct dipolar interaction does not influence the positions of peaks in liquid phase NMR spectra. It can also be shown that for isolated spin pairs in solid samples the time averaged expectation value of $\hat{\mathcal{H}}_{DD}$ is zero under conditions of MAS.¹² The sample must be spun rapidly with respect to the direct dipolar coupling constant R .

In order to discuss the NMR spectrum of two dipolar coupled spins in the solid state, it is convenient to transform equation (5) from Cartesian coordinates to spherical polar coordinates. This is readily accomplished by setting: $x = r \sin \theta \cos \phi$, $y = r \sin \theta \sin \phi$, $z = r \cos \theta$ and expressing $\hat{I}_x$ and $\hat{I}_y$ in terms of the raising and lowering operators $\hat{I}^+$ and $\hat{I}^-$, respectively:

$$\hat{I}^+ = \hat{I}_x + i\hat{I}_y, \quad \hat{I}^- = \hat{I}_x - i\hat{I}_y \quad (14)$$

Spin functions used to describe a nuclear spin state are eigenfunctions of the Zeeman Hamiltonian; they are often denoted by $|I, m\rangle$, where I is the nuclear spin quantum number and m is the z component of the spin angular momentum in units of $\hbar$ (i.e. $\hat{I}_z |I, m\rangle = m|I, m\rangle$). The spin quantum number m may take on values of $-I, -I+1, \dots, +I$. Thus, for spin- $\frac{1}{2}$ nuclei there are only two states $|\frac{1}{2}, \frac{1}{2}\rangle$ and $|\frac{1}{2}, -\frac{1}{2}\rangle$, which are generally denoted by $|\alpha\rangle$ and $|\beta\rangle$, respectively: $\hat{I}_z |\alpha\rangle = \frac{1}{2}|\alpha\rangle$ and $\hat{I}_z |\beta\rangle = -\frac{1}{2}|\beta\rangle$, while $\hat{I}^+ |\alpha\rangle = 0$, $\hat{I}^+ |\beta\rangle = |\alpha\rangle$, $\hat{I}^- |\alpha\rangle = |\beta\rangle$ and $\hat{I}^- |\beta\rangle = 0$. Further details concerning the quantum mechanics of angular momentum can be found elsewhere.^{8-11, 13, 14}

In spherical polar coordinates, the dipolar Hamiltonian can be expressed in terms of the so-called dipolar alphabet:

$$\hat{\mathcal{H}}_{DD} = hR(\hat{A} + \hat{B} + \hat{C} + \hat{D} + \hat{E} + \hat{F}) \quad (15)$$

Each of the terms $\hat{A}$ to $\hat{F}$ contains spin operators and a spatial term generally involving both θ and ϕ . Each term alters the spin functions used to describe a spin pair in a characteristic way. Explicit expressions for the terms $\hat{A}$ to $\hat{F}$ are given in several NMR textbooks.⁸⁻¹¹

To describe the NMR spectrum of a pair of equivalent homonuclear spins in a strong magnetic field, it is only necessary to consider the terms $\hat{A}$ and $\hat{F}$:

$$\hat{A} = -\hat{I}_{1z}\hat{I}_{2z}(3\cos^2\theta - 1) \quad (16)$$

$$\hat{B} = \frac{1}{4}[\hat{I}_1^+ \cdot \hat{I}_2^- + \hat{I}_1^- \cdot \hat{I}_2^+](3\cos^2\theta - 1) \quad (17)$$

Clearly, the $\hat{A}$ term does not alter the simple product spin functions $|\alpha\alpha\rangle$, $|\alpha\beta\rangle$, $|\beta\alpha\rangle$, and $|\beta\beta\rangle$ (e.g. $\hat{I}_{1z}\hat{I}_{2z}|\alpha\beta\rangle = (\frac{1}{2})(-\frac{1}{2})|\alpha\beta\rangle$). On the other hand, the $\hat{B}$ term contains the ‘flip-flop’ operator $\hat{I}_1^+\hat{I}_2^- + \hat{I}_1^-\hat{I}_2^+$, which alters the spin functions $|\alpha\beta\rangle$ to $|\beta\alpha\rangle$, and vice versa. For a pair of magnetically equivalent spins which are dipolar coupled in a strong applied magnetic field $\mathbf{B}_0$, the appropriate Hamiltonian operator is

$$\hat{\mathcal{H}} = \hat{\mathcal{H}}_Z + \hat{\mathcal{H}}_{DD} \quad (18)$$

where $\hat{\mathcal{H}}_Z = -\nu_0 h(\hat{I}_{1z} + \hat{I}_{2z})$, and $\nu_0 = \gamma B_0/2\pi$. To describe such a spin system, it is convenient to use the following basis functions:

$$|t_1\rangle = |\alpha\alpha\rangle \quad (19a)$$

$$|t_0\rangle = 2^{-1/2}(|\alpha\beta\rangle + |\beta\alpha\rangle)$$

$$|s\rangle = 2^{-1/2}(|\alpha\beta\rangle - |\beta\alpha\rangle) \quad (19b)$$

$$|t_{-1}\rangle = |\beta\beta\rangle \quad (19c)$$

Using these basis functions, the total matrix of the truncated dipolar Hamiltonian operator is diagonal. The resulting eigenvalues of $\hat{\mathcal{H}}$ (in frequency units) are:

$$|t_1\rangle : -\nu_0 - \frac{1}{4}R(3\cos^2\theta - 1) \quad (20a)$$

$$|t_0\rangle : \frac{1}{2}R(3\cos^2\theta - 1) \quad (20b)$$

$$|t_{-1}\rangle : \nu_0 - \frac{1}{4}R(3\cos^2\theta - 1) \quad (20c)$$

$$|s\rangle : 0 \quad (20d)$$

where θ is the angle between the dipolar vector and the applied magnetic field $\mathbf{B}_0$. Transitions involving the antisymmetric $|s\rangle$ level are symmetry-forbidden; therefore only two transitions, $\nu_0 \pm \frac{3}{4}R(3\cos^2\theta - 1)$, are allowed.

For any general orientation of a spin pair in an applied magnetic field, the two peaks are separated by $(\frac{3}{2})R(3\cos^2\theta - 1)$. Spectra from an isolated homonuclear spin pair in a hypothetical single crystal and powder sample are shown in Figure 2. The powder spectrum, known as a Pake powder pattern, is obtained by considering all orientations of the dipolar vector in $\mathbf{B}_0$ ($0^\circ \leq \theta \leq 180^\circ$; $0^\circ \leq \phi \leq 360^\circ$). The separation between the discontinuities, $(\frac{3}{2})R$, corresponds to $\theta = 90^\circ$ while the shoulders are separated by $3R$, which corresponds to the $\theta = 0^\circ$ orientation.

For a pair of unlike spins A and X, where the two spins have different magnetogyric ratios but both are spin $\frac{1}{2}$, it is only necessary to consider the A term of $\hat{\mathcal{H}}_{DD}$ since this is the only term in the dipolar alphabet which commutes with $\hat{\mathcal{H}}_Z$. The A-spin NMR spectrum consists of two peaks at $\nu_A \pm (\frac{1}{2})R(3\cos^2\theta - 1)$, where $\nu_A = \gamma_A B_0/2\pi$; the X-spin spectrum will be identical, except for the fact that it is centered about ν_X instead of ν_A . For unlike spins, the separation between the discontinuities in the A-spin or X-spin Pake powder pattern is R . If the X spin is a quadrupolar nucleus, calculation of the A-spin NMR spectrum may be more difficult, particularly if the high-field approximation is not applicable [i.e. $\hat{\mathcal{H}}_Z(X) \approx \hat{\mathcal{H}}_Q(X)$]. An instructive example of this problem was provided by Stoll et al.¹⁵ who discussed the ^{13}C NMR spectra of the $^{13}\text{C} - ^{14}\text{N}$ spin pair in a single crystal of $\text{K}_2\text{Pt}(\text{CN})_4\text{Br}_{0.3} \cdot 3\text{H}_2\text{O}$.

In practice, the chemical shielding interaction is orientation dependent, and thus it will also influence the detailed NMR lineshape. For protons, anisotropic chemical shielding generally causes a minor perturbation on the Pake doublet powder pattern, since it will be several orders of magnitude smaller than the direct dipolar interaction. However, for most other nuclei, the anisotropic chemical shielding (in frequency units) may be comparable to or greater than the dipolar interactions with adjacent nuclei. Under such conditions the

Figure 2 Calculated NMR spectra for two equivalent spins $\hat{I}_1$ and $\hat{I}_2$ which interact with one another by the direct dipolar interaction. From top to bottom: calculated spectra for three orientations of the internuclear vector in the applied magnetic field B_0 , $\theta = 0^\circ, 45^\circ, 90^\circ$, respectively. The bottom spectrum is the Pake powder pattern which results from a sum of spectra of individual crystallites which are randomly distributed in the sample. The calculated spectra have been convoluted with a Gaussian function to simulate weak dipolar interactions with more remote nuclei

‘A’-spin NMR spectrum of an AX-spin system in a static powder sample will consist of $2I + 1$ overlapping powder patterns, where I is the spin quantum number of X (Figure 3). One can often obtain valuable information concerning the orientation of chemical shielding tensors by analyzing dipolar chemical shift NMR spectra.^{14,16–18}

Typical values of the direct dipolar coupling constant involving directly bonded spin pairs range from a few hundred hertz to several kilohertz. For example, for the directly bonded ^{13}C – ^{15}N spin pair in the amide fragment of a peptide, $R \approx 1.3$ kHz; for the directly bonded ^{13}C – ^1H spin pair in a typical organic compound, $R \approx 23$ kHz. Further examples of direct dipolar coupling constants involving carbon are given in Table 1.

Much recent research is being focused on recoupling of dipolar interactions in high-resolution MAS experiments, e.g. the rotational resonance and rotational echo double resonance (REDOR) techniques.^{19–21} The objective of these experiments is to determine internuclear separations from small dipolar coupling constants. In fact, as will be outlined in Section 3.2, these experiments yield only an effective dipolar coupling constant

Figure 3 (a) A typical spin- $\frac{1}{2}$ NMR powder pattern of an isolated spin with anisotropic chemical shielding. The principal components of the chemical shielding tensor are easily identified from the powder pattern by the shoulders at σ_{11} and at σ_{33} and the discontinuity at σ_{22} . (b) Same as (a), but the influence of direct dipolar coupling with an adjacent spin- $\frac{1}{2}$ nucleus is illustrated. The direct dipolar interaction causes an apparent splitting of the chemical shielding powder pattern

Table 1 Typical Direct and Indirect Spin–Spin Coupling Constants Involving Carbon

X	Compound	R^a (Hz)	$J(\text{M}, ^{13}\text{C})_{\text{iso}}$ (Hz)	$K(\text{M}, \text{C})_{\text{iso}}^b$
^{13}C	$\text{C}(\text{CH}_3)_4^c$	2080	37	4.9

which is dependent on the anisotropy in the indirect coupling as well as the direct dipolar coupling constant R .

As an aside, it is important to indicate that anisotropic molecular vibrations can result in a subtle vibrationally induced asymmetry of the dipolar coupling tensor; this will be most important when the direct dipolar coupling involves a hydrogen nucleus.^{22,23}

The discussion presented here can be extended to more complex spin systems. For example, Van Hecke et al.²⁴ studied the ^1H and ^{19}F NMR spectra of the bifluoride ion in a single crystal of KHF_2 . In addition, systems containing the $^{13}\text{CH}_2$ fragment have attracted considerable attention.^{25–27}

3 INDIRECT SPIN–SPIN COUPLING

As mentioned in Section 1, indirect spin–spin coupling is a two-stage process. One can imagine the spin at one nucleus perturbing the electrons in its vicinity. The resulting

perturbation is transferred via the electronic framework of the molecule to electrons in the vicinity of the second nucleus. The distinctive ways in which a nuclear moment perturbs the surrounding electrons is known as a mechanism for indirect spin–spin coupling (see below). The total indirect spin–spin coupling constant J is a sum of the contributions arising from each mechanism. Clearly, the contribution that each coupling mechanism makes to J is directly proportional to the product of the nuclear magnetic moments of the two coupled nuclei. The sign of indirect spin–spin coupling constants can be either positive or negative. If the indirect spin–spin coupling interaction stabilizes the antiparallel arrangement of the nuclear spins, then the indirect spin–spin coupling is positive. The magnitudes of isotropic indirect spin–spin coupling constants are readily measured in solution NMR studies. Values as small as 0.10 Hz are routinely measured. Isotropic values rarely exceed 30 kHz; however, a ^{199}Hg , ^{199}Hg indirect spin–spin coupling constant of 139.6 kHz has been reported for the Hg_3^{2+} ion.²⁸ Typical values of one-bond indirect spin–spin coupling constants involving carbon, $^1J(\text{M}, ^{13}\text{C})_{\text{iso}}$, are given in Table 1. The literature on isotropic indirect spin–spin coupling constants is extensive.²⁹ Over the past 45 years many important relationships between spin–spin coupling constants J_{iso} and molecular structure have been established. On the other hand $\mathbf{J}$ tensors are difficult to characterize experimentally. Furthermore, reliable quantum mechanical calculations of $\mathbf{J}$ tensors or their corresponding isotropic values are a challenge.³⁰ Here, the properties of the $\mathbf{J}$ tensor are outlined. This is followed by a discussion of how the $\mathbf{J}$ tensor can be experimentally characterized from solid state NMR measurements.

3.1 Nature of $\mathbf{J}$ Coupling Tensors

The Hamiltonian describing the indirect spin–spin coupling of two spins, $\mathbf{I}_1$ and $\mathbf{I}_2$, may be expressed as

$$\hat{\mathcal{H}}_J = h \hat{\mathbf{I}}_1 \cdot \mathbf{J} \cdot \hat{\mathbf{I}}_2 \quad (21)$$

where $\mathbf{J}$ is the indirect spin–spin coupling tensor. The $\mathbf{J}$ tensor is a second rank tensor which is described by nine matrix elements in a Cartesian coordinate system. For example, in a particular molecular fixed axis system, the $\mathbf{J}$ tensor might be represented by the matrix:

$$\mathbf{J} = \begin{bmatrix} J_{aa} & J_{ab} & J_{ac} \\ J_{ba} & J_{bb} & J_{bc} \\ J_{ca} & J_{cb} & J_{cc} \end{bmatrix} \quad (22)$$

In contrast to the direct dipolar tensor, the $\mathbf{J}$ tensor has a nonvanishing trace.

A general second-rank tensor can be decomposed into a sum of irreducible tensors of rank $l = 0, 1, 2$.^{31,32} Thus the indirect spin–spin coupling tensor can be written as

$$\mathbf{J} = \mathbf{J}^{(0)} + \mathbf{J}^{(1)} + \mathbf{J}^{(2)} \quad (23)$$

In equation (23) the $l = 0$ tensor is the isotropic part of the tensor,

$$\mathbf{J}^{(0)} = \left(\frac{1}{3} \text{Tr } \mathbf{J}\right) \mathbf{1} = J_{\text{iso}} \mathbf{1} \quad (24)$$

where $\text{Tr } \mathbf{J} = (J_{aa} + J_{bb} + J_{cc})$ and $\mathbf{1}$ is the unit tensor with diagonal components equal to 1 and all off-diagonal elements zero. The second term in equation (23), $l = 1$, is the antisymmetric part of the tensor,

$$\mathbf{J}^{(1)} = \frac{1}{2}(\mathbf{J} - \mathbf{J}^t) \quad (25)$$

where $\mathbf{J}^t$ is the transpose of $\mathbf{J}$. The transpose of a 3×3 matrix is obtained by replacing the first column by the first row, the second column by the second row, and the third column by the third row. Since the diagonal elements of $\mathbf{J}$ and $\mathbf{J}^t$ are identical, the diagonal elements of the antisymmetric tensor are zero. The third term in equation (23), $l = 2$, is the symmetric part of the tensor, defined as

$$\mathbf{J}^{(2)} = \frac{1}{2}(\mathbf{J} + \mathbf{J}^t) - J_{\text{iso}} \mathbf{1} \quad (26)$$

Although the trace of the symmetric part is zero, the diagonal elements are, in general, not zero.

To a very good approximation, only tensors with $l = 0$ and $l = 2$ affect the general appearance of an NMR spectrum.³² That is, even though the antisymmetric components of a particular $\mathbf{J}$ tensor may be non zero, these components do not perturb the observed spectrum in first order. In fact, the existence of antisymmetric components in any indirect spin–spin coupling tensor has never been demonstrated experimentally.³³

For each symmetric $\mathbf{J}$ tensor ($\mathbf{J}^{(0)} + \mathbf{J}^{(2)}$), there exists a principal axis system for which the matrix $\mathbf{J}^{(2)}$ is diagonal. The diagonal elements, denoted by J_{xx} , J_{yy} , and J_{zz} , are called the principal elements, with the convention:

$$|J_{zz}| \geq |J_{xx}| \geq |J_{yy}| \quad (27)$$

The principal axis system of the $\mathbf{J}$ tensor is often fixed by the molecular symmetry. For a linear molecule there are only two components, $J_{\parallel}$ and $J_{\perp}$, describing the coupling of the nuclear spin components parallel and perpendicular to the internuclear axis, respectively. Similarly, there are only two non-zero components of the symmetric $\mathbf{J}$ tensor for a pair of nuclei sitting on the highest order symmetry axis of molecules in the point groups D_{nd} , D_{nh} , C_{nh} , C_{nv} , and S_n , with $n \geq 3$. The number of independent components in the $\mathbf{J}$ tensor for other group symmetries has been tabulated by Buckingham et al.³³ and by Robert and Wiesenfeld.³⁴

In describing the orientation dependence of NMR parameters, it is often useful to define the anisotropy of the parameter. This provides a measure of the maximum orientation dependence of that particular parameter. The anisotropy of the indirect spin–spin coupling tensor is usually defined as

$$\Delta J = J_{zz} - \frac{1}{2}(J_{xx} + J_{yy}) \equiv \frac{3}{2}(J_{zz} - J_{\text{iso}}) \quad (28)$$

In the case of axial symmetry, equation (28) simplifies to

$$\Delta J = J_{\parallel} - J_{\perp} \quad (29)$$

In such cases it is straightforward to show that

$$\mathbf{J} = \begin{bmatrix} J_{\perp} & 0 & 0 \\ 0 & J_{\perp} & 0 \\ 0 & 0 & J_{\parallel} \end{bmatrix} = J_{\text{iso}} \mathbf{1} + \begin{bmatrix} -\Delta J/3 & 0 & 0 \\ 0 & -\Delta J/3 & 0 \\ 0 & 0 & 2\Delta J/3 \end{bmatrix} \quad (30)$$

Under these conditions the Hamiltonian equation (21), becomes

$$\hat{\mathcal{H}}_{\mathbf{J}} = hJ_{\text{iso}}\hat{\mathbf{I}}_1 \cdot \hat{\mathbf{I}}_2 + h\hat{\mathbf{I}}_1 \cdot \mathbf{J}' \cdot \hat{\mathbf{I}}_2 \quad (31)$$

where $\mathbf{J}'$ is the traceless ‘ $\Delta\mathbf{J}$ ’ tensor which is of the same form as the dipolar tensor [equation (13)]. Since the trace of $\mathbf{J}'$ is zero, it is clear that the anisotropy in the principal components of $\mathbf{J}$ has no influence on the NMR spectra of isotropic fluids. In principle, ΔJ could provide a mechanism for spin–lattice relaxation, but this mechanism has never been identified as being important.³⁵

Ramsey’s theory⁵ serves as the basis for most theoretical discussions of indirect spin–spin coupling tensors. Following Ramsey, the nonrelativistic Hamiltonian describing nuclear spin, electron spin interactions can be represented by

$$\hat{\mathcal{H}} = \hat{\mathcal{H}}^{(1a)} + \hat{\mathcal{H}}^{(1b)} + \hat{\mathcal{H}}^{(2)} + \hat{\mathcal{H}}^{(3)} \quad (32)$$

The first two terms are the so-called orbital diamagnetic (OD) and orbital paramagnetic (OP) terms which account for the interaction between the nuclear magnetic moments and the orbital motion of the electrons. The third term, $\hat{\mathcal{H}}^{(2)}$, accounts for the spin-dipolar (SD) interactions between the nuclear and electronic magnetic moments. The last term, $\hat{\mathcal{H}}^{(3)}$, accounts for the interaction of the nucleus and the electron spin at the nucleus; this interaction is known as the Fermi contact (FC) interaction. Using these interactions, various approaches, generally based on second-order perturbation theory, are used to calculate indirect nuclear spin–spin coupling tensors. Five separate terms contribute to the overall $\mathbf{J}$ tensor:

$$\mathbf{J} = \mathbf{J}^{(1a)} + \mathbf{J}^{(1b)} + \mathbf{J}^{(2)} + \mathbf{J}^{(3)} + \mathbf{J}^{(4)} \quad (33)$$

The orbital diamagnetic contribution $\mathbf{J}^{(1a)}$ involves only the ground electronic state of the system. The other four terms involve the following combination of interactions: OP–OP, SD–SD, FC–FC, and FC–SD. The OP term has matrix elements between the ground state and excited singlet states while the SD and FC interactions have matrix elements between the ground state and excited triplet states. The FC–FC contribution to the $\mathbf{J}$ tensor is completely isotropic. In contrast, the FC–SD cross term does not contribute to the isotropic value of the spin–spin coupling tensor, but only to its anisotropy, thus the trace of the tensor arising from this term is zero. The other two terms contribute to both the isotropic and anisotropic portion of the total $\mathbf{J}$ tensor.

Explicit expressions for each of the five terms in equation (33) are given in several standard NMR texts and review articles.^{29,36} It should be mentioned that the theory of Ramsey is a nonrelativistic theory which assumes that orbital and spin angular momenta are L – S coupled. Pyykkö³⁷ has developed a relativistic analogue of Ramsey’s theory based on j – j coupling. Undoubtedly, relativistic effects will be important for indirect spin–spin coupling constants involving nuclei beyond the second row. Furthermore, it has been found that consideration of relativistic effects in extended Hückel calculations tends to increase the calculated anisotropy of spin–spin coupling tensors.³⁸

In equation (33), each term is of the form $\gamma_N\gamma_{N'}/h\mathbf{K}_{N,N'}/4\pi^2$, where $\mathbf{K}_{N,N'}$ is called the reduced indirect

spin–spin coupling tensor involving nuclei N and N' . The reduced coupling tensor is independent of the magnitude of the nuclear magnetic moments and, therefore, it is useful in comparing indirect spin–spin coupling tensors involving different spin pairs. Note that $\mathbf{J}_{N,N'}$ has units of Hz (s^{-1}) and $\mathbf{K}_{N,N'}$ has units of $\text{N A}^{-2} \text{m}^{-3}$ (or, equivalently, $\text{T}^2 \text{J}^{-1}$).³⁹ The isotropic indirect spin–spin coupling constants involving carbon in Table 1 have also been expressed as reduced coupling constants. As one descends the group 14 elements, M , of the Periodic Table in the series $M(\text{CH}_3)_4$, $\mathbf{K}(M, \text{C})$ increases with atomic number Z_M . Similarly, in the series $X_3\text{MPR}_3$, where M is a group 13 element, $\mathbf{K}(M, \text{P})$ increases as follows: $\approx 10 \times 10^{20} \text{N A}^{-2} \text{m}^{-3}$ ($M = \text{B}$), $\approx 20 \times 10^{20} (\text{Al})$, $\approx 65 \times 10^{20} (M = \text{Ga})$, and $\approx 100 \times 10^{20} (M = \text{In})$.⁴⁰ Qualitatively, these trends can be rationalized by considering only the Fermi contact mechanism; however, there is evidence that the tensor, $\mathbf{K}(\text{In}, \text{P})$, in $\text{Br}_3\text{InP}[4-(\text{CH}_3\text{O})-\text{C}_6\text{H}_4]_3$ is anisotropic, implying that mechanisms other than the Fermi contact contribute to this particular $\mathbf{J}$ tensor.⁴⁰

3.2 Measurement of $\mathbf{J}$ Coupling Tensors

Using NMR spectroscopy, $\mathbf{J}$ tensors can be characterized by studying the spectra of single crystals,^{41–43} solid powder samples,^{44–47} or samples oriented in liquid crystalline solvents.^{48,49} In isotropic fluids, only the isotropic indirect spin–spin coupling constant (a scalar) is measured. For simple molecules in the gas phase ΔJ can, in principle, be measured using molecular beam magnetic resonance techniques.⁵⁰ So far, the latter technique has only been successfully applied to thallium fluoride.⁵¹ In this case, $J(^{205}\text{Tl}, ^{19}\text{F})_{\text{iso}} = -13.3 \pm 0.7 \text{ kHz}$ and $\Delta J(^{205}\text{Tl}, ^{19}\text{F}) = 11.1 \pm 0.7 \text{ kHz}$. Below, the NMR spectra of a simple heteronuclear two-spin system residing in a rigid solid will be discussed. Particular emphasis is placed on describing how the NMR spectra depend on ΔJ .

Consider a pair of heteronuclear spins A and X , also denoted by ‘1’ and ‘2’, respectively, which are coupled to one another via direct and indirect spin–spin interactions in a strong applied magnetic field. Furthermore, if the $\mathbf{J}$ tensor is axially symmetric and coincident with the direct dipolar tensor, $J_{\parallel}$ and $J_{\perp}$ correspond to orientations where the internuclear vector is parallel and perpendicular, respectively, to the applied magnetic field. Under these conditions the appropriate nuclear spin Hamiltonian for the A spin is:

$$\hat{\mathcal{H}} = \hat{\mathcal{H}}_Z + \hat{\mathcal{H}}_{\text{CS}} + \hat{\mathcal{H}}_{\text{DD}} + \hat{\mathcal{H}}_J \quad (34)$$

where $\hat{\mathcal{H}}_{\text{CS}}$ accounts for the anisotropic chemical shielding. For now it is assumed that the chemical shielding is independent of the orientation of the molecule in the applied magnetic field. Both $\hat{\mathcal{H}}_{\text{DD}}$ and $\hat{\mathcal{H}}_J$ are of the same form. As already indicated

$$\hat{\mathcal{H}}_{\text{DD}} = hR\hat{\mathbf{I}}_1 \cdot \mathbf{D} \cdot \hat{\mathbf{I}}_2 = -hR\hat{I}_{1z}\hat{I}_{2z}(3\cos^2\theta - 1) \quad (35)$$

Similarly, equation (31) becomes

$$\begin{aligned} \hat{\mathcal{H}}_J &= h\hat{\mathbf{I}}_1 \cdot \mathbf{J} \cdot \hat{\mathbf{I}}_2 = hJ_{\text{iso}}\hat{I}_{1z}\hat{I}_{2z} + h(\Delta J/3)\hat{I}_{1z}\hat{I}_{2z} \\ &\quad \times (3\cos^2\theta - 1) \end{aligned} \quad (36)$$

Using the basic product functions for an AX spin system consisting of two spin- $\frac{1}{2}$ nuclei, it is straightforward to calculate the four energy levels. The A spectrum results from two allowed transitions at:

$$\nu = \nu_A - m_X J_{\text{iso}} + m_X [R - (\Delta J/3)](3 \cos^2 \theta - 1) \quad (37)$$

where $m_X = +\frac{1}{2}$ or $-\frac{1}{2}$. The two A peaks are separated by

$$\Delta \nu = J_{\text{iso}} - [R - (\Delta J/3)](3 \cos^2 \theta - 1) \quad (38)$$

Often, the term $R - (\Delta J/3)$ in equations (37) and (38) is called the effective dipolar coupling constant R_{eff} ; thus,

$$\Delta \nu = J_{\text{iso}} - R_{\text{eff}}(3 \cos^2 \theta - 1) \quad (39)$$

The splittings, $\Delta \nu$, that would be observed as the A-X bond axis, r_{AX} , in a single crystal is rotated about an axis perpendicular to B_0 are shown in Figure 4. Several important points emerge from equations (37)–(39) and Figure 4:

1. For a single crystal sample, equation (39) also applies if the chemical shielding is anisotropic.
2. From Figure 4 it is apparent that the maximum variation in the splitting of the A peaks is $3R_{\text{eff}}$. Experimentally, one cannot separately determine R and ΔJ ; only R_{eff} can be measured. If a value for the internuclear separation r_{AX} can be determined independently by diffraction techniques, R can be calculated from equation (11), and ΔJ can be obtained from the experimental value of R_{eff} .
3. The relative sign of J_{iso} and R_{eff} can be deduced from single crystal measurements. If J_{iso} and R_{eff} have the same sign, the maximum splitting will be $|J_{\text{iso}}| + |R_{\text{eff}}|$, while the minimum splitting will be $|J_{\text{iso}}| - 2|R_{\text{eff}}|$. On the other hand, if J_{iso} and R_{eff} have opposite signs, the maximum splitting will be $|J_{\text{iso}}| + 2|R_{\text{eff}}|$ and the minimum splitting will be $|J_{\text{iso}}| - |R_{\text{eff}}|$.

Figure 4 Separation between the two allowed A spin transitions for an AX spin system in a single crystal as a function of the orientation in the applied magnetic field B_0 . Splittings are given in units of R_{eff} . The rotation axis is perpendicular to B_0 and the rotation angle θ is defined as the angle between r_{AX} and B_0

Figure 5 The effect of ΔJ on the A-spin NMR spectrum of a powder sample containing a heteronuclear AX spin pair. In each case $J_{\text{iso}} = 5R$. With $\Delta J = 3R$, each subspectrum collapses into an isotropic peak

In the case of a powder sample, the A spectrum consists of two subspectra corresponding to $m_X = +\frac{1}{2}$ and $m_X = -\frac{1}{2}$. Each subspectrum is one-half of a conventional Pake powder pattern (Figure 5). The isotropic frequencies of the two subspectra are separated by J_{iso} . (Note that if $J_{\text{iso}} = 0$, conventional Pake powder patterns would be observed except for the case where $\Delta J = 3R$.)

In calculating the spectra shown in Figure 5, the chemical shielding is assumed to be isotropic (i.e. independent of orientation). In order to calculate the A-spin NMR powder lineshape, allowing for the possibility of anisotropic chemical shielding, it is convenient to define the orientation of the internuclear vector in the PAS of the chemical shielding tensor (Figure 6). In this case one can show that the frequency of the A-spin transitions are given by:

$$\nu_m(\theta, \phi) = \nu_L - \nu_{\text{CS}} - m_X \nu_D - m_X J_{\text{iso}} \quad (40)$$

$$\nu_L = \gamma_A B_0 / 2\pi \quad (41)$$

$$\nu_{\text{CS}} = \left(\frac{\gamma_A B_0}{2\pi} \right) (\sigma_{11} \sin^2 \theta \cos^2 \phi + \sigma_{22} \sin^2 \theta \sin^2 \phi + \sigma_{33} \cos^2 \theta) \quad (42)$$

$$\nu_D = R_{\text{eff}} \{ 1 - 3[\sin \beta \sin \theta \cos(\phi - \alpha) + \cos \beta \cos \theta]^2 \} \quad (43)$$

Figure 6 The orientation of an internuclear vector r_{AX} in the principal axis system (PAS) of the A-spin shielding tensor. The angles θ and ϕ define the orientation of B_0 in the PAS of the shielding tensor

where the principal components of the chemical shielding tensor σ_{11} , σ_{22} , and σ_{33} are defined such that $\sigma_{11} \leq \sigma_{22} \leq \sigma_{33}$. All angles are defined in Figure 6. In deriving equations (40)–(43), it is assumed that the $\mathbf{J}$ tensor is axially symmetric and that the $\mathbf{J}$ and $\mathbf{D}$ tensors are coincident. Even with these assumptions, the A-spin NMR powder spectrum may prove difficult to analyze.¹⁸

From the above discussion, it should be clear that if one is interested in characterizing a particular $\mathbf{J}$ tensor using solid state NMR techniques, single crystal NMR studies are desirable. Unfortunately, few studies have been reported to date.^{41–43} Such studies are generally tedious, require relatively large single crystals (e.g. sides of 1 mm or greater), and the results of an X-ray or neutron diffraction investigation. In some cases, values of ΔJ can be obtained from the analysis of NMR powder spectra which arise from isolated spin pairs.^{44–47} For example, for a series of mercury phosphine complexes values of $\Delta J(^{199}\text{Hg}, ^{31}\text{P})$ of the order of 5 kHz have been estimated from the analysis of static ^{31}P NMR spectra.^{46,47} Below, the general procedure used to analyze such spectra is outlined.

The ^{31}P CP MAS spectrum of one of these complexes, $[\text{HgP}(o\text{-tolyl})_3(\text{NO}_3)_2]_2$, is shown in Figure 7. The natural abundance of ^{199}Hg is 16.84% ($I = \frac{1}{2}$), therefore the ^{31}P NMR spectrum of the molecules containing the ^{199}Hg – ^{31}P spin pair is a doublet with separation $J(^{199}\text{Hg}, ^{31}\text{P})_{\text{iso}} = 9660$ Hz. The sign of this indirect spin–spin coupling constant is assumed to be positive on the basis of double resonance NMR experiments carried out on related molecules in solution. The only other naturally occurring isotope of mercury with nonzero spin is ^{201}Hg ($I = \frac{3}{2}$; natural abundance 13.22%), but the ^{31}P NMR spectrum of the ^{201}Hg – ^{31}P spin pair is very broad and difficult to observe at room temperature. Molecules containing other naturally occurring isotopes of mercury give rise to a single isotropic peak, since the mercury nuclei of these isotopes have $I = 0$. In order to obtain R_{eff} , it is most advantageous to obtain a ^{31}P NMR spectrum of a static powder sample (Figure 8). Again, the intense central feature in the ^{31}P NMR spectrum corresponds to molecules where mercury nuclei have a spin $I = 0$.

Analysis of this central lineshape provides the principal components of the phosphorus shielding tensor, information required to analyze the subspectra arising from the ^{199}Hg – ^{31}P spin pairs. In this case, the phosphorus shielding tensor is

Figure 7 The ^{31}P NMR spectrum of a powder sample of $[\text{HgP}(o\text{-tolyl})_3(\text{NO}_3)_2]_2$ obtained with relatively slow magic angle sample spinning ($\nu_r = 892$ Hz). The spectrum was obtained with high-power ^1H decoupling and cross polarization in an applied magnetic field of 4.7 T, corresponding to a ^{31}P NMR Larmor frequency of 81.0 MHz. Frequencies are given with respect to the isotropic ^{31}P NMR peak of solid $\text{NH}_4\text{H}_2\text{PO}_4$. The horizontal arrow indicates the separation between the isotropic peak positions of the ^{199}Hg satellite peaks ($J_{\text{iso}} = 9660$ Hz). Note that the spinning sidebands of the high-frequency satellite peak, $m_{\text{Hg}-199} = -\frac{1}{2}$, extend over a much larger range than do those of the low-frequency satellite corresponding to $m_{\text{Hg}-199} = \frac{1}{2}$

Figure 8 The ^{31}P NMR spectrum of a static powder sample of $[\text{HgP}(o\text{-tolyl})_3(\text{NO}_3)_2]_2$ obtained at 81.0 MHz

approximately axially symmetric with the unique component along the Hg–P bond axis. Inspection of the spectrum shown in Figure 8 indicates that the high-frequency subspectrum corresponding to $m_{\text{Hg}-199} = -\frac{1}{2}$ is stretched (breadth ≈ 4.75 kHz), while the low-frequency subspectrum corresponding to $m_{\text{Hg}-199} = \frac{1}{2}$ is squeezed (breadth ≈ 1.45 kHz) relative to the intense central powder pattern $[(\nu_{\parallel} - \nu_{\perp}) \approx 3.10$ kHz]. In this particular case it is straightforward to show that the

Figure 9 Calculated ^{31}P NMR powder spectra of $[\text{HgP}(o\text{-tolyl})_3(\text{NO}_3)_2]_2$ as a function of ΔJ . The direct dipolar coupling constant, $R = 0.64$ kHz, and $(\nu_{\parallel} - \nu_{\perp}) \approx 3.10$ kHz were held constant in each calculation. The central uncoupled ^{31}P NMR spectrum is only shown in the top spectrum; its intensity has been suppressed to emphasize the variations in the satellite subspectra as a function of ΔJ

breadth of each subspectrum is given by

$$\Delta\nu_{\pm m(\text{Hg}-^{199})} = (\nu_{\parallel} - \nu_{\perp}) \pm 3m_{\text{Hg}-^{199}}R_{\text{eff}} \quad (44)$$

Solving equation (44), one obtains $R_{\text{eff}} = -1.10$ kHz. From the known values of $r_{\text{Hg-P}}$ in closely related compounds, $R = 0.64$ kHz; thus $(\Delta J/3) = 1.74$ kHz and $\Delta J = 5.2$ kHz. Note that if the relative signs of R_{eff} and J_{iso} were not known, another acceptable solution would be $R_{\text{eff}} = +1.10$ kHz, hence $\Delta J = -1.38$ kHz. The sensitivity of the ^{31}P NMR spectrum of $[\text{HgP}(o\text{-tolyl})_3(\text{NO}_3)_2]_2$ to ΔJ is illustrated in Figure 9. A complete single crystal ^{31}P NMR study of a closely related compound, $\text{HgP}(\text{cyclohexyl})_3(\text{NO}_3)_2$, has recently been completed.⁵² A typical rotation pattern is shown in Figure 10. Analysis indicates that $R_{\text{eff}} = -1.07$ kHz, leading to comparable values of $\Delta J(^{199}\text{Hg}, ^{31}\text{P})$.⁵² The results of these studies are significant in that they indicate that mechanisms other than the Fermi contact contribute to the $\mathbf{J}(^{199}\text{Hg}, ^{31}\text{P})$ tensor.

For AX spin systems in powder samples, one can also obtain R_{eff} from slow spinning MAS or variable angle spinning NMR studies; however, the errors tend to be large. Therefore, unless R_{eff} is significantly different than R , any estimate of ΔJ may be meaningless.

If a spin- $\frac{1}{2}$ nucleus is coupled to a neighboring quadrupolar nucleus, the spin- $\frac{1}{2}$ MAS NMR lineshape will often exhibit

Figure 10 Plot of $\Delta\nu - J(^{199}\text{Hg}, ^{31}\text{P})_{\text{iso}}$ versus the rotation angle for a single crystal of $\text{HgP}(\text{cyclohexyl})_3(\text{NO}_3)_2$. In this case the rotation axis is approximately perpendicular to the vector $r_{\text{Hg-P}}$ so that the maximum observed variation in frequency (3.21 kHz) is approximately $3R_{\text{eff}}$

residual ‘dipolar splittings’ due to coupling with the quadrupolar nucleus.⁵³ In such cases the magic angle is no longer ‘magic’ because of the breakdown of the high-field approximation. Qualitatively, the Zeeman states of the quadrupolar nuclei are perturbed by the quadrupolar interaction. Thus, the detailed spin- $\frac{1}{2}$ MAS NMR lineshape depends on R_{eff} , B_0 , the nuclear quadrupolar coupling constant, and the orientation of the EFG tensor at the quadrupolar nucleus with respect to R_{AX} . Unless information concerning the EFG tensor at the quadrupolar nucleus is available from independent NMR or NQR studies, analysis of the spin- $\frac{1}{2}$ MAS NMR spectrum will be problematic.

Information concerning ΔJ is also available from NMR studies of solute molecules partially ordered in liquid crystalline solvents; however, again one can only determine R_{AX} . In fact, from such experiments one measures a parameter which is related to $-S_{zz}[R - (\Delta J/3)]$, where S_{zz} is an order parameter, typically of the order of 0.1. In addition, it is necessary to make vibrational corrections and consider solute–liquid crystal solvent interactions. In spite of these problems, reliable values of ΔJ appear to be available for several compounds. For example, for methyl fluoride, $\Delta J(^{19}\text{F}, ^{13}\text{C}) = 404 \pm 31$ Hz, and thus $\Delta J(^{19}\text{F}, ^{13}\text{C})/J(^{19}\text{F}, ^{13}\text{C})_{\text{iso}} = -2.5 \pm 0.2$;⁵⁴ for dimethylmercury, $\Delta J(^{199}\text{Hg}, ^{13}\text{C}) = 855 \pm 14$ Hz, and thus $\Delta J(^{199}\text{Hg}, ^{13}\text{C})/J(^{199}\text{Hg}, ^{13}\text{C})_{\text{iso}} = 1.25 \pm 0.02$.⁵⁵

As mentioned in Section 2, several NMR experiments have been developed to recouple the direct dipolar interaction under conditions of MAS. Although such experiments actually measure R_{eff} , and not R , it is probably reasonable to assume that $(\Delta J/3) \ll R$, if the coupled nuclei are both first row elements (e.g. ^{13}C and ^{15}N), where J_{iso} is probably at least an order of magnitude less than R . Clearly, reliable theoretical calculations could be of value in assessing the validity of this assumption for any given spin pair.

Finally, it is of interest to mention that, several years ago, Andrew and Farnell⁵⁶ investigated the effect of magic angle sample spinning on each of the irreducible tensors which describe the indirect spin–spin coupling tensor [equation (23)]. Of course, MAS does not influence the term $\mathbf{J}\mathbf{1}$; also, the traceless symmetric components do not influence

the MAS spectrum. However, for a homonuclear spin pair, they found that MAS will not necessarily result in a complete averaging of the antisymmetric components of the $\mathbf{J}$ tensor [i.e. components of $\mathbf{J}^{(1)}$ in equation (23)]. The contribution of the antisymmetric components was predicted to be most important when the chemical shift difference between the two coupled spins was very small. Further discussions of the possibility of measuring antisymmetric components of the $\mathbf{J}$ tensor are given in the excellent review by Robert and Wiesenfeld.³⁴ As already mentioned, the antisymmetric components of any indirect spin–spin coupling tensor have not been experimentally characterized.

4 SUMMARY

From the experimental point of view, it is clear that the mathematical properties of the anisotropic indirect $\mathbf{J}$ tensor are analogous to those of the direct dipolar tensor. As a result, it is impossible to measure separately the anisotropic $\mathbf{J}$ tensor and the direct dipolar tensor. Fortunately, for isolated spin pairs in rigid solid samples, the direct dipolar tensor can always be calculated if structural data are available. The most reliable procedure for characterizing $\mathbf{J}$ tensors in the solid state involves single crystal NMR experiments. For solid powder samples the determination of ΔJ is often problematic. The reliability of a powder analysis will always be greatest when: (i) the spin pair of interest lies along a symmetry axis, (ii) J_{iso} is large enough so that the individual subspectra are well resolved, and (iii) R is small or at least comparable to $\Delta J/3$. With the availability of higher sensitivity NMR hardware and advanced single crystal NMR experiments one can hope that more reliable experimental data will become available. In the future, one can also anticipate significant advances in computational techniques, particularly for relatively small molecules involving atoms of the first two rows of the Periodic Table. Unfortunately, these are the systems where it is most difficult to obtain reliable experimental data concerning the anisotropy in the $\mathbf{J}$ tensor. In any case, it is clear that in order to formulate meaningful models relating J couplings to molecular structure, a better understanding of the $\mathbf{J}$ tensor is essential. Obviously, any information that indicates which mechanisms are or are not operative is critically important in leading to a better understanding of J coupling phenomena.

1 INTRODUCTION

Distance geometry is a general methodology which formulates conformational problems in terms of distance and chirality constraints.¹ It has been applied to such diverse problems as the conversion of two-dimensional chemical diagrams into three-dimensional structures, the systematic enumeration of all possible stereoisomers and conformers of small molecules, the docking of ligands to their receptors, and the construction of protein models by homology. It also plays a central role in present-day methods for determining the solution structures of proteins and other biological macromolecules from NMR data. There are several reasons for this. First, NMR spectroscopy, particularly the NOESY experiment, provides a wealth of data that are readily interpreted in terms of distance constraints. Second, although the problem of finding atomic coordinates consistent with distance constraints is a highly nonlinear one, unlike the problem of locating the global energy minimum it can nevertheless be solved quite reliably. Third, since the global minima of the functions that are minimized in distance geometry should have the value zero, the distance geometry formulation of the structure determination problem makes it relatively straightforward to find errors in the interpretation of the data.

2 GEOMETRIC REASONING WITH DISTANCE INFORMATION

Newcomers to distance geometry should be careful not to confuse it with the least-squares fits that are widely used in crystallography. Instead of seeking a *single* ‘best fit’ to the data as in the least-squares method, the goal of distance geometry is to understand better the set of all conformations consistent with the data as a whole. This is done by deriving new geometric facts about the molecule from those that are available experimentally, in a process known more generally as *geometric reasoning*. There are several ways of going about this, as described below.

2.1 Describing Molecular Conformation

A *distance geometry description* defines the set of possible conformations of a nonrigid molecule by means of lower and upper bounds on its interatomic distances, together with the chiralities of its rigid tetrahedra of atoms. The set of conformations consistent with these constraints itself is called *conformation space*. Such a description is usually not chemically complete, meaning that there may be conformations in the space that do not exist in appreciable concentration under the conditions of interest. It may also contain noncritical constraints, i.e. constraints that could be tightened without reducing the conformation space consistent with them, or it may contain redundant constraints, i.e. constraints that could be loosened or eliminated without enlarging the space.

The distance constraints may come from many sources. Clearly, the molecular formula (bond arrangement) is one of them, since both covalent bond lengths as well as the geminal distances which define the bond angles are determined essentially exactly by this information. Many other distances can also be fixed within larger rigid groups of atoms, e.g. aromatic ring systems. In addition, the distance between all pairs of atoms separated by four or more bonds may be assumed to be at least the sum of suitable hard sphere atomic radii, and other noncovalent interactions, e.g. hydrogen bonds, can also be modeled by means of distance constraints. Finally, distance constraints are available from many kinds of experiment, including optical fluorescence transfer, various noncrystallographic diffraction experiments and, of course, NMR spectroscopy. As a general rule, one should collect as many constraints as possible, since even redundant constraints are useful in distance geometry calculations.

The most obvious case in which chirality constraints are needed is at asymmetric carbon atoms, since the distances between their neighboring atoms cannot be used to distinguish enantiomers. It turns out that chirality constraints are also useful in many other cases. For example, prochiral centers should usually be constrained in distance geometry calculations, against the possibility that stereospecific assignments may be available, and chirality constraints among α -carbon atoms can be used to enforce the handedness of α -helices. Planarity can also be viewed as a sort of chirality constraint (neither left- nor right-handed), which is applicable to most double bonds. Finally, although the absolute value of a torsion angle about the 2,3-bond in a chain of four atoms can be determined by specifying the 1,4-distance, its sign can only be fixed by also constraining the chirality of the tetrahedron the vertices of which are these four atoms.

In solution, by far the richest source of distance constraints is the two-dimensional NMR experiment NOESY. Since the nuclear Overhauser effect (NOE) that this experiment measures is due to dipole–dipole interactions, the intensity of a cross peak in a NOESY spectrum is roughly proportional to the average inverse sixth power of the distance between a pair of protons in the molecule. This means that (provided a short enough mixing time is used to eliminate the possibility of indirect NOEs) the mere presence of such a cross peak implies that the maximum distance between the protons is quite small, 0.50 nm at the most. Because the NOE is also proportional to a factor that depends on the unknown average

rate at which the interproton vector reorients (and may, in addition, be influenced by many other sources of relaxation), a more quantitative interpretation of the cross-peak intensities is difficult. Fortunately, as discussed in the last section of this article, in the important special case of globular proteins a reasonably precise and well-defined structure can often be obtained without quantifying most of the NOESY cross-peak intensities.

2.2 Inconsistent Distance Constraints

The task of collecting, processing, and interpreting NMR data, particularly on large molecules such as proteins in solution, is a complex one which is susceptible to many sources of systematic as well as random error. The distance geometry approach attempts to distinguish between these two types of error by interpreting the data geometrically in terms of constraints that are intended to encompass the *full range* consistent with the intrinsic uncertainty of the measurements due to thermal noise, intramolecular motion, and similar phenomena. Assuming (as is often the case) that the data are sufficiently complete and precise to determine a nearly unique conformation, any serious errors in the interpretation of some of the data will usually cause the constraints as a whole to become mutually *inconsistent*. This means that it is impossible to satisfy the constraints by any single conformation, which in turn implies that one or more of the assumptions made in interpreting the data must be false. Although the inconsistencies can be arbitrarily complex, in most cases it is possible to isolate them to relatively small subsets of atoms, meaning that the constraints among those atoms are by themselves inconsistent with any three-dimensional structure.

Any method of detecting inconsistencies in the constraints also makes it possible to falsify structural hypotheses, and thereby opens up one possible route towards geometric reasoning. Certain relatively simple ‘patterns’ of inconsistent constraints can not only be detected, but also isolated, by a process known as ‘bound smoothing’ (see below). More often, however, inconsistency can only be detected by repeatedly trying to calculate a conformation consistent with the constraints, and failing. Since the currently available algorithms for doing this are quite reliable, this situation strongly implies that the constraints are inconsistent. Unfortunately, the minimization procedures commonly used to calculate conformations result in a compromise between violations of the correct as well as the incorrect constraints, which makes it relatively difficult to isolate inconsistency by this approach, although there is a significant correlation between the frequency and severity of constraint violations and the correctness of the constraints.

2.3 Bound Smoothing and Distance Limits

An important class of distance geometry algorithms are designed to perform *bound smoothing*. These play a central role in the so-called EMBED algorithm (see Section 3.4), but the distance limits that bound smoothing algorithms compute are of much broader interest, and hence are described here. A more complete description, together with a detailed presentation of the algorithms themselves, is available.¹

The three-dimensional *distance limits* associated with any set of distance bounds are simply the minimum and maximum value that each distance can assume in any spatial structure the other distances of which all lie within their given bounds. Since the distance bounds available from NMR spectroscopy are necessarily imprecise and very sparse, computing the corresponding distance limits can reveal a great many consequences of the NMR data that are not obvious from direct inspection, thus providing another approach to geometric reasoning. The distance limits also enable one to detect redundant and critical distance constraints, since by definition the distance limits for redundant bounds are tighter than those bounds, while the distance limits for critical bounds are looser. Finally, the distance bounds as a whole are inconsistent if and only if the limits implied by the bounds among some subset of atoms violate the bounds, i.e. a lower bound exceeds its upper limit, or vice versa.

Unfortunately, the computation of the true three-dimensional distance limits is a difficult and unsolved problem, and only loose approximations are readily available. These are the limits implied by the bounds among subsets of three or four atoms at a time, which are known as the *triangle inequality* and *tetrahedron inequality limits*, respectively (Figure 1). These can be computed in time proportional to at most the cube, and at least the fourth power, of the number of atoms, respectively. Although much weaker than the true three-dimensional limits, particularly with regard to the lower limits, they are capable of revealing considerable redundancy in many sets of distance constraints, and they often succeed in catching typographical errors committed during data entry that otherwise could be located only after careful proofreading or long calculation.

Figure 1 Schematic drawing of the triangle (top) and tetrahedron (middle and bottom) limits; the upper limits are shown on the left half and the lower limits on the right. In these diagrams, solid lines indicate distances at their lower bounds, thick dotted lines indicate distances at their upper bounds, and thin dotted lines indicate the limit determined by this combination of bounds. Thus, for example, the upper left diagram indicates that the upper triangle inequality limit on the distance between the endpoints is obtained when the two distances to the midpoint are stretched to their upper bounds. The complete set of triangle or tetrahedron limits may be obtained by iteratively replacing the bounds by the corresponding limits whenever these are tighter, until no further changes occur

Figure 2 The triangle inequality limits among the α -carbon atoms of the 58 residue protein BPTI (above the diagonal), together with the distance matrix obtained from its crystal structure (below the diagonal). The rows and columns of this combined matrix are ordered in the same way as the corresponding residues in the BPTI sequence, and the cells are shaded according to the value of the corresponding limit or distance. The correlation between the upper limits and the distances is obvious

Another important use of the triangle (or tetrahedron) limits is as a means of predicting various structural features prior actually to calculating any structures. Although this can, in principle, be done with any sort of molecule, we shall concentrate here on the important case of globular proteins subject to NOESY distance constraints. Contoured plots of the distances among the α -carbon atoms have long been used as a visual aid to recognizing the secondary structure 'topology' of globular proteins. Moreover, there exists a strong positive correlation between the upper triangle limits and the actual distances (even when only a few NOESY constraints per residue are available).² Therefore, contoured plots of the upper limits can serve much the same purpose as distance matrices, and it is possible to determine the chain fold and other basic features of a protein from NMR data at a very early stage in the analysis. This in turn should facilitate that analysis. Figure 2 shows an example of such a contour plot for the protein basic pancreatic trypsin inhibitor (BPTI), along with its distance matrix.

2.4 The Ensemble Approach

Bound smoothing constitutes an example of *deductive* geometric reasoning. Another, in some ways even more important approach may be called *inductive* geometric reasoning. Here, one computes an *ensemble* of conformations which satisfy the constraints, but are otherwise 'random'. Then, provided that this conformational ensemble is sufficiently large (meaning, for most purposes, 10 to 20 conformations), any geometric features that are uniformly present in all its members may safely be assumed to be necessary consequences of the constraints. The geometric features of interest are not limited to distances,

but may include angles, chiralities, and far more subtle things such as the radius of gyration, surface accessibility or chain 'topology'. They may also include properties of the ensemble as a whole, such as the average or maximum 'difference' between any two conformations.

In structure determination by NMR spectroscopy, the most widely used measure of the difference between two conformations is the root mean square coordinate deviation (RMSD). This is simply the root mean square difference in their coordinate vectors (or equivalently, the root mean square distance between corresponding pairs of atoms) minimized over all translations and rotations of one conformation with respect to the other. This quantity may be computed among all the atoms, or among any desired subset (e.g. the α -carbons atoms of a protein). The average of the RMSD over all pairs of conformations in the ensemble is often used as a measure of the overall precision of an NMR structure determination, with 0.10 nm generally regarded as good, 0.20 nm as fair and 0.30 nm or more as poor. One should nevertheless be careful not to read too much into this single number. It is far more important to determine exactly how the conformations in the ensemble differ from one another than it is to determine by how much they differ on average. Fortunately, the translation and rotation which gives the RMSD also allows one to

Figure 3 Stereoview of an ensemble of 25 BPTI conformations computed from a set of simulated NMR distance constraints using the program DGII.⁴ These conformations (thin gray lines) have been superimposed on the crystal structure from which the constraints were derived (heavy black line) so as to minimize the RMSD to its α -carbon atoms, for an average RMSD of 0.085 nm

superimpose the structures so as to visualize easily their detailed differences by computer graphics (Figure 3).

Another commonly studied geometric feature is the torsion angles about single bonds. The precision of such cyclic parameters is best quantitated by means of an average value and ‘order parameter’, which is defined as follows. Given a single bond in the molecule, one puts a unit vector down in the plane for each conformation in the ensemble, whose angle with the x axis is equal to the value of the corresponding torsion angle in that conformation. On summing these unit vectors and dividing by the size of the ensemble, one obtains an average vector whose angle with the x axis is the average of the torsion angle, and whose length is the corresponding order parameter. This angular order parameter is unity only if the angle has exactly the same value in all conformations, and approaches zero as the angle becomes random.

3 DISTANCE GEOMETRY ALGORITHMS

Here the term ‘distance geometry algorithm’ is used somewhat loosely for any procedure that helps us to perform computer-aided geometric reasoning with distance and chirality constraints (including torsion angle constraints). Because of their utility in NMR studies of solution conformation, we concentrate here on algorithms for computing conformational ensembles. Several, rather different approaches have been taken to this problem, each of which has its advantages and disadvantages, but all of which have been successfully applied to large molecules. Rather than attempting an exhaustive survey, the discussion is limited to those algorithms which have been most widely used by NMR spectroscopists to date, or which appear particularly promising.

3.1 Restraints and Error Functions

A common feature of all these algorithms is that they rely on minimization of an error function, which measures the violations of the constraints.^{1,3,4} As such, an error function is always non-negative, and zero if, and only if, all the constraints are fully satisfied. The construction of an error function involves translating the constraints into *restraints*, that is, into functions of a single geometric parameter that force that parameter to satisfy its constraint when they are minimized. The error function is then obtained as the sum over all restraints.

A simple example of such a function is

$$E(\mathbf{p}_1, \dots, \mathbf{p}_N) = \sum \left[\max \left(0, \frac{d_{ij}^2}{u_{ij}^2} - 1 \right) \right]^2 + \sum \left[\max \left(0, 1 - \frac{d_{ij}^2}{l_{ij}^2} \right) \right]^2 + \sum C_{ijkl}^2(\mathbf{p}_1, \dots, \mathbf{p}_N) \quad (1)$$

where u_{ij} and l_{ij} denote the upper and lower distance bounds, and $C_{ijkl}^2(\mathbf{p}_1, \dots, \mathbf{p}_N)$ is a chirality restraint, which is described below. Squaring the distance restraints ensures that the

function has continuous first derivatives, as required by many minimization algorithms, while scaling them by the inverse-squared bounds ensures that the various restraints receive roughly equal weight, which tends to make minimization of the error function somewhat easier. Ideally, however, the results should be independent of the assumed weights.

The chirality restraints, which are ordinarily needed only when Cartesian coordinates are used as the variables (see below), are usually defined as

$$C_{ijkl}^2(\mathbf{p}_1, \dots, \mathbf{p}_N) = [\text{vol}(\mathbf{p}_i, \mathbf{p}_j, \mathbf{p}_k, \mathbf{p}_l) - v_{ijkl}]^2 \quad (2)$$

Here

$$\text{vol}(\mathbf{p}_i, \mathbf{p}_j, \mathbf{p}_k, \mathbf{p}_l) = (\mathbf{p}_i - \mathbf{p}_l) \cdot [(\mathbf{p}_j - \mathbf{p}_l) \times (\mathbf{p}_k - \mathbf{p}_l)] \quad (3)$$

is the oriented volume of the four atoms whose Cartesian coordinates are $\{\mathbf{p}_i, \mathbf{p}_j, \mathbf{p}_k, \mathbf{p}_l\}$, and v_{ijkl} is its target value. The well-known properties of the vector triple product imply that the oriented volume has absolute value equal to six times the volume of the tetrahedron spanned by the four atoms, and that its sign is positive for one chirality of this tetrahedron, negative for its mirror image, and zero whenever the atoms are coplanar.

There are two distinct ways of parameterizing the space of atomic configurations over which the minimizations must be carried out. The first uses three independent Cartesian coordinates for each atom, while the second uses the torsion angles about single bonds as the variables. The latter has the advantage of reducing the number of variables by about a factor of 10, which greatly improves the performance of many minimization algorithms. It also enables one to impose torsion angle constraints simply and directly, and maintains the covalent geometry automatically without the use of constraints on the bonded and geminal distances. As a consequence, however, it is not possible to correct violations of these constraints, which limits the methods that can be used to derive good starting structures for the minimizations. In addition, torsion angle optimizations are relatively complicated to implement, particularly if flexible rings are present in the molecules of interest. Both parameterizations are widely used in computational chemistry.

3.2 The Variable Target Function Algorithm

The variable target function algorithm was developed by Braun and Gö⁵ specifically for the purpose of computing the structures of proteins using distance constraints derived from NMR spectroscopy. By repeating the calculation many times, each time starting from a different set of randomly chosen torsion angles, one obtains the desired conformational ensemble. The method has been under continuous development since its introduction, and has become an effective tool for determining protein structures using distance and torsion angle constraints derived from NMR data. A survey of the early structures solved by this method is available.⁶

3.2.1 Avoiding Local Minima by Variable Target Functions

Even though torsion-based optimizations are quite efficient at converging to local minima, when used to solve distance geometry problems it is essential to find a global minimum of the error function. With large molecules such as proteins, the number of local minima is so large that this is highly unlikely to be achieved in any given run starting from a random conformation. The essential idea behind the variable target function approach is to avoid becoming trapped in local minima by initially minimizing a target (i.e. error!) function that restrains only the torsion angles together with the ‘short-range’ distances between neighboring amino acid residues, and gradually adding on longer and longer range restraints. In this way the ‘short-range’ or secondary structure is formed first, after which the secondary structural elements are docked together to form the tertiary structure, in a fashion that is analogous to the way in which proteins are widely believed to fold in solution. Although this heuristic method does not guarantee that a global minimum will be attained in any given run, it does increase the convergence ratio enough essentially to ensure that, with a little persistence, a global minimum with zero error will be found if one exists.

Because they require memory that grows only linearly with the size of the molecule, first-derivative based minimization methods such as conjugate gradients are generally used with the variable target function algorithm. The number of minimization iterations performed at each stage (restraint range) must be determined largely by trial and error, but does not seem to vary greatly from one protein to another. As a rule, it has been found more efficient to increase the range of the upper distance restraints obtained from NMR more rapidly than the lower distance restraints obtained as the sum of the hard-sphere radii (or, roughly equivalently, to weight the NMR restraints more strongly than the hard-sphere restraints in the initial stages), probably because the NMR restraints are far more effective at determining the tertiary structure than are the hard-sphere restraints. The method is particularly effective at determining the structures of proteins whose secondary structure consists primarily of α -helices, where the convergence ratio may approach 100%. With β -sheets or irregular structures, the convergence ratio can drop below 10%. This effectively lowers the efficiency of the method by a factor of 10, since nonconverging structures must be discarded and the minimization repeated until the desired number of conformations has been obtained.

3.2.2 Further Improvements in Speed and Reliability

The time required for each function/gradient evaluation is generally dominated by the time required to find all the hard-sphere overlaps, especially in the final stages of the variable target function algorithm when most of the hard-sphere restraints are considered. This can be greatly alleviated by using either grid-based or list-based methods to avoid checking most pairs of atoms for overlap. The hard-sphere overlap check, as well as much of the rest of the algorithm, has also been efficiently vectorized, so that each run can be performed very rapidly on a supercomputer.⁷ The convergence ratio can be improved by choosing the torsion angles of the starting structure for the minimization from within their allowed ranges, rather than completely at random. These ranges can

be reduced, and stereospecific assignments elucidated, by grid search methods which find those combinations of angles in each single residue that are consistent with the intraresidue distance constraints.⁸ More recently, it has been suggested that the throughput can be greatly improved by imposing the ranges of angles observed in converged segments of nonconverged structures as constraints in subsequent calculations.⁹ Finally, a minimization procedure has been proposed which, though apparently less efficient than conjugate gradients, yields error bounds on the torsion angles in the final conformations.¹⁰

3.3 Simulated Annealing and Related Methods

A second class of methods rely on a very general approach to global optimization problems known as simulated annealing. In this case, one treats the error function as an energy function, and uses either molecular dynamics or other methods to sample conformations with a Boltzmann distribution at a given absolute temperature. By slowly lowering the temperature, the distribution gradually narrows into a single energy minimum, and as in crystallization and similar physical processes this minimum will often be a global minimum. Because of the numerous error function calculations required, many of the above-mentioned methods of accelerating these calculations are also used in simulated annealing.

3.3.1 Dynamical Simulated Annealing

One way to generate conformations with a Boltzmann distribution is via molecular dynamics. This is a general method for simulating the evolution of molecular systems under the influence of a classical Hamiltonian $\mathcal{H}$, by iteratively solving Newton’s equations of motion:

$$m_i \frac{d^2 \mathbf{p}_i}{dt^2} = -\nabla \mathcal{H} \quad (4)$$

This may be done by using either the ‘leap-frog’ algorithm

$$v_i[(2k+1)\Delta t/2] = v_i[(2k-1)\Delta t/2] - \Delta t \frac{\nabla \mathcal{H}}{m_i} \quad (5a)$$

$$\mathbf{p}_i[(k+1)\Delta t] = \mathbf{p}_i(k\Delta t) + \Delta t v_i[(2k+1)\Delta t/2] \quad (5b)$$

or the Verlet algorithm

$$\mathbf{p}_i[(k+1)\Delta t] = 2\mathbf{p}_i(k\Delta t) + \mathbf{p}_i[(k-1)\Delta t] - (\Delta t)^2 \frac{\nabla \mathcal{H}}{m_i} \quad (6)$$

In the first applications of this method to NMR structure determination problems,^{11,12} the error due to the NMR restraints was added to an empirical energy function, and the combined function treated as the Hamiltonian of the system. This had several disadvantages. First, the strong forces between bonded and overlapping atoms necessitated the use of a small time step, which in turn meant that a large number of function and gradient evaluations were needed to reach equilibrium at any given temperature. Second, the function and gradient evaluations themselves required a relatively large quantity of computer time, because the forces involved in

empirical energy functions are relatively long range. Third, careful weighting of the NMR restraints was necessary in order to keep them from ‘drowning out’ the energy, or vice versa.

Despite these problems, by changing the weights of the short- and long-range restraints versus the energy as the annealing proceeded in a fashion similar to that used in the variable target function algorithm, impressive results were attained, including the folding of small proteins starting from a completely random array of atoms.¹³ Subsequently, it was found that the efficiency and reliability of the calculations could be further improved by dropping the energy entirely, and treating a simple error function as the Hamiltonian.^{14,15} In fact, in most cases the energy has little effect on the spread of the resulting conformational ensembles as measured by the average RMSD,¹⁶ although it does tend to sharpen the distribution of the torsion angles noticeably. As a rule, however, this can be achieved more efficiently by energy minimization once the overall structure has been determined.¹⁷

Although in actual attempts to simulate the physical evolution of chemical systems it is essential to keep the time step small enough to accurately conserve the energy of the system, when molecular dynamics is used as a heuristic for simulated annealing we have found it advantageous to use the largest possible time step consistent with numerical stability.⁴ A further improvement in efficiency can be attained by using the same mass for all the atoms, since numerical stability prevents the time step from being made much longer than the inverse rate of the fastest bond vibration. The temperature of the system can be controlled by rescaling the velocities, or by simulating a temperature bath via a temperature dependent viscosity term. Annealing has also been achieved by slowly making all the force constants larger, until the system becomes essentially rigid at a fixed temperature. While molecular dynamics can be performed using the torsion angles as the variables, such simulations are relatively uncommon and have only recently been applied to NMR structure determination problems. Further information on dynamical simulated annealing, and its applications to both NMR and crystallographic structure determination, may be found in recent reviews.¹⁸

3.3.2 Other Stochastic Optimization Methods

The classical method of generating atomic configurations with a Boltzmann distribution, known as the *Monte Carlo method*,¹⁹ dates back to the earliest days of scientific computing. This method does not use gradient information, and is applicable to either Cartesian coordinates, torsion angles, or even to discrete (combinatorial) optimization problems.²⁰ While several applications of Monte Carlo based simulated annealing to energy minimization have been reported, only one application to NMR structure determination has been published to date.²¹ The reason is that the usual implementations appear to be substantially less efficient than the dynamical simulated annealing method described above. The efficiency and reliability of the Monte Carlo method, however, hinges critically on the rate at which the temperature is lowered and the way in which the positions of the atoms are perturbed in each iteration. Recently, a variety of sophisticated methods have been developed for energy minimization purposes, which generate larger changes with a better chance of being accepted.^{22–24} It therefore seems likely that a Monte

Carlo procedure could be devised that performs reasonably efficiently with distance geometry problems.

Another class of stochastic minimization methods that appear suitable for distance geometry problems are known as *genetic algorithms*. Unlike the methods described above, which are based on a physical analogy, genetic algorithms are based on an analogy with the optimization of the ‘fitness’ of populations by natural selection. These methods have actually been available for some years,²⁵ but have only recently begun to attract widespread interest.²⁶ Once again, the basic procedure is simple, but the efficiency and reliability depend critically on how the basic steps are implemented. Using torsion angles as the variables, these procedures have recently been successfully applied to energy minimization problems,²⁷ as well as at least one distance geometry problem involving NMR data.²⁸ Genetic algorithms have the attractive feature of intrinsically computing ensembles of conformations, and hence, if reasonably good ways of implementing the basic steps can be found, they may prove to be an improvement over other torsion angle based algorithms.

3.4 The EMBED Algorithm and its Variations

The EMBED algorithm is a method of randomly generating the Cartesian coordinates of structures that roughly fit the distance constraints, and hence are good starting points for minimization by any method that is applicable to Cartesian coordinates. It was actually developed^{3,29} prior to the development of two-dimensional NMR, as part of a larger effort to demonstrate the applicability of distance geometry to a wide variety of experimental and theoretical information.³⁰ Shortly thereafter, it was employed to determine the conformation of fragments of micelle-bound glucagon from NMR data,³¹ and then to determine the first protein solution structure ever solved by NMR.¹⁷ It has since been used in the determination of more protein, DNA, and other biomolecular structures than the space available here permits us to present.

Structure calculations with the EMBED algorithm consist of three basic steps:

1. Using bound smoothing algorithms to estimate the best possible limits on the distances from the sparse and imprecise set of distance bounds given as input.
2. Guessing a random set of distances from within the limits, and computing Cartesian coordinates such that the distances calculated from these coordinates are a best fit to this guess.
3. Optimizing these coordinates by minimization of an error function so that both the distance and chirality constraints are satisfied.

By repeating steps (2) and (3) with different random number seeds in step (2), one obtains the desired conformational ensemble. Although all three steps have traditionally been considered to be part of the EMBED algorithm, steps (1) and (3) are of independent interest (as described above). For this reason we prefer to restrict our usage of the term to step (2). Since any method for minimizing error functions with respect to Cartesian coordinates can be used in step (3), the EMBED algorithm should be understood as being complementary to these methods, rather than a substitute for them. Indeed, the combination of the EMBED algorithm with simulated annealing is presently one of the most efficient and reliable methods available for NMR structure determination.^{4,32}

3.4.1 Random Distance Matrices by Metrization

Early implementations of the EMBED algorithm generated their random distance matrices by choosing the trial distances $[\tilde{d}_{ij}]$ independently of one another with a uniform distribution from within their limits. It was subsequently found that, when the density of distance constraints was quite low, the coordinates obtained in this way were uniformly expanded compared with those obtained by other methods. This undesirable tendency is eliminated by *metrization*, an extension of triangle inequality bound smoothing that enables one to choose random distance matrices which obey the triangle inequality from within the triangle inequality limits.^{33,34} In principle, by making the trial distances more realistic, this should also improve the quality of the embedded coordinates.

Metrization itself is based on a characterization of the triangle inequality limits which shows that if any distance is set to any value between its triangle inequality limits, values exist for the remaining distances so that all the distances satisfy both the triangle inequality and the limits. Thus by alternately setting one distance to some random value between its limits, then setting the corresponding lower and upper bounds to that distance and updating the limits by this change, one will eventually obtain a complete distance matrix satisfying both the triangle inequality and the limits. Provided that one uses a data structure known as a ‘shortest-paths tree’ to store the limits involving one atom, these updates can be accomplished in time proportional to the number of atoms, so that the overall time required is proportional to its cube.

Because triangle bound smoothing is more effective at lowering upper bounds than it is at raising lower bounds, it is necessary to randomize the order in which the atoms are considered for each metrization, in order to avoid having some parts of the structure come out systematically more compact than others. In applications to distance constraints derived from NMR data, it is also desirable to control the distribution with which the distances are selected so as to obtain average values that asymptotically tend towards some fixed fraction of the upper limits, since this ensures a correlation between the distances and the upper limits similar to that observed in practice (see Figure 2).

3.4.2 Embedding Distance Matrices

The trial distances chosen randomly from within the distance limits in the previous step are essentially always inconsistent, and hence cannot be realized by any possible conformation of the molecule. Nevertheless, if we can find coordinates that are a ‘best fit’ to these distances, then since the distances satisfy the constraints, the coordinates ought to at least come close. It turns out that a certain type of best fit can be rapidly calculated by eigenvalue methods.

To see how this works, suppose we are given a matrix of squared distances among a set of $N + 1$ points $\mathbf{p}_0, \dots, \mathbf{p}_N$, in three-dimensional space:

$$\mathbf{D} = [d_{ij}^2] = [\|\mathbf{p}_i - \mathbf{p}_j\|^2] \quad (7)$$

The symmetric, $N \times N$ matrix of dot products of the vectors from the zeroth point to all the rest is usually called the *metric*

or *Gram matrix* $\mathbf{G}$, and can be calculated directly from $\mathbf{D}$ via the well-known law of cosines:

$$\mathbf{G} = [(\mathbf{p}_i - \mathbf{p}_0) \cdot (\mathbf{p}_j - \mathbf{p}_0)] = \frac{1}{2}[d_{0i}^2 + d_{0j}^2 - d_{ij}^2] \quad (8)$$

Let $\mathbf{G} = \mathbf{U}\mathbf{\Lambda}\mathbf{U}^T$ denote the eigenvalue decomposition of $\mathbf{G}$, where $\mathbf{U}$ is the orthogonal matrix whose columns are the eigenvectors of $\mathbf{G}$ and $\mathbf{\Lambda} = \text{diag}(\lambda_1, \dots, \lambda_N)$ is a diagonal matrix containing its real eigenvalues sorted by decreasing value. Since $\mathbf{G} = \mathbf{P}^T\mathbf{P}$, where $\mathbf{P} = [\mathbf{p}_1 - \mathbf{p}_0, \dots, \mathbf{p}_N - \mathbf{p}_0]$ is a $3 \times N$ matrix, the matrix $\mathbf{G}$ is positive semidefinite of rank at most 3, so that $\lambda_1 \geq \lambda_2 \geq \lambda_3 \geq 0$ and $\lambda_4, \dots, \lambda_N = 0$. Thus if we define the 3×3 diagonal matrix $\mathbf{\Lambda}_3^{1/2} = \text{diag}(\lambda_1^{1/2}, \lambda_2^{1/2}, \lambda_3^{1/2})$ together with the $3 \times N$ matrix:

$$\mathbf{Q} = [\mathbf{q}_1, \dots, \mathbf{q}_N] = \mathbf{\Lambda}_3^{1/2}[\mathbf{u}_1, \mathbf{u}_2, \mathbf{u}_3]^T = \mathbf{\Lambda}_3^{1/2}\mathbf{U}_3^T \quad (9)$$

it follows that the points $\mathbf{q}_0 = 0$ and $\mathbf{q}_1, \dots, \mathbf{q}_N$ have the same Gram matrix as $\mathbf{p}_0, \dots, \mathbf{p}_N$:

$$\begin{aligned} \mathbf{G} &= (\mathbf{U}_3\mathbf{\Lambda}_3^{1/2})(\mathbf{\Lambda}_3^{1/2}\mathbf{U}_3^T) = \mathbf{Q}^T\mathbf{Q} = [\mathbf{q}_i \cdot \mathbf{q}_j] \\ &= [(\mathbf{q}_i - \mathbf{q}_0) \cdot (\mathbf{q}_j - \mathbf{q}_0)] \end{aligned} \quad (10)$$

They also have the same distance matrix, since $\|\mathbf{p}_i - \mathbf{p}_0\|^2 = g_{ii} = \|\mathbf{q}_i - \mathbf{q}_0\|^2$ for $i = 1, \dots, N$, while for all $0 \neq i \neq j \neq 0$, we have:

$$\begin{aligned} \|\mathbf{p}_i - \mathbf{p}_j\|^2 &= \|\mathbf{p}_i - \mathbf{p}_0\|^2 + \|\mathbf{p}_j - \mathbf{p}_0\|^2 - 2[(\mathbf{p}_i - \mathbf{p}_0) \cdot (\mathbf{p}_j - \mathbf{p}_0)] \\ &= \|\mathbf{q}_i\|^2 + \|\mathbf{q}_j\|^2 - 2(\mathbf{q}_i \cdot \mathbf{q}_j) = \|\mathbf{q}_i - \mathbf{q}_j\|^2 \end{aligned} \quad (11)$$

Therefore, the new points are the same as the old up to translation and/or rotation, so that $\mathbf{q}_0, \dots, \mathbf{q}_N$ can be regarded as $\mathbf{p}_0, \dots, \mathbf{p}_N$ in a new coordinate system. Moreover, it follows from the orthogonality of the eigenvectors that these new coordinates are principal axes coordinates.

Although principal axes coordinates can be found more efficiently by diagonalizing the inertial tensor, the above method is applicable even if we do not have any coordinates for the points, but only the distances among them. The problem is that if the distances are inconsistent, the approximate Gram matrix $\tilde{\mathbf{G}}$ computed from the squared trial distances $\tilde{\mathbf{D}} = [\tilde{d}_{ij}^2]$ according to equation (8) will not be positive semidefinite of rank 3, and hence cannot be represented as a matrix of dot products among three-dimensional vectors. It can be shown, however, that if one sets all but the three largest eigenvalues to zero, then the matrix $\mathbf{G}$ obtained via equation (10) will be an optimum least-squares fit to $\tilde{\mathbf{G}}$ over all positive semidefinite rank 3 matrices.¹ It follows that the squared distances calculated from the coordinates

$$\|\mathbf{q}_i - \mathbf{q}_j\|^2 = g_{ii} + g_{jj} - 2g_{ij} \approx \tilde{g}_{ii} + \tilde{g}_{jj} - 2\tilde{g}_{ij} = \tilde{d}_{ij}^2 \quad (12)$$

will likewise be similar to the squared trial distances $\tilde{\mathbf{D}}$.

Note that the diagonal elements of the approximate Gram matrix $\tilde{g}_{ii} = \tilde{d}_{0i}^2$, which are just the squared trial distances involving the zeroth point, affect the fit to all the other

distances. This disproportionate influence can be eliminated by creating an additional point located at the centroid of the remaining N points, and treating it as the zeroth point. This is possible because the distances from the centroid to the remaining points can be calculated directly from the distances among them via the equation²⁹

$$\tilde{d}_{0i}^2 = \frac{1}{N} \sum_{j=1}^N \tilde{d}_{ij}^2 - \frac{1}{N^2} \sum_{j < k}^N \tilde{d}_{jk}^2 \quad (13)$$

Even so, the EMBED algorithm does not produce exactly a least-squares fit between the trial distances and those calculated from the coordinates. The coordinates obtained by embedding, however, can easily be improved by minimization of an appropriately weighted least-squares residual, using a method known as *majorization*.⁴

Because a variety of extremely efficient methods exist to locate the largest few eigenvalues and eigenvectors of a symmetric matrix without completely diagonalizing it, the EMBED algorithm is by far the fastest known way of finding reasonably good approximate coordinates to serve as starting points for further optimization.

3.4.3 Variations on Embedding

In the years since it was developed, the EMBED algorithm has been improved and extended in many ways, some of which have been touched on above. In this section several recent developments which promise to be useful in NMR structure determination are described.

The first of these methods is derived from early work by Crippen, who applied ideas from the EMBED algorithm to energy minimization.^{1,35} Since the EMBED algorithm can be viewed geometrically as projecting a higher dimensional structure onto a three-dimensional subspace, Crippen proposed minimizing the energy of the structures in spaces of successively lower dimension, eventually reaching a very low energy minimum constrained to three dimensions. He calls this approach *energy embedding*. Because even the simple conjugate gradients minimization of error functions converges quite reliably in four dimensions, it appears that only four dimensions are needed in applications of this approach to distance geometry. Unfortunately, it also turns out that the reduction of a four-dimensional structure to three dimensions is the most difficult step of the procedure, probably because it is in this step that the chirality and diastereomeric configuration of the molecule is determined.

Several investigators have found that by applying dynamical simulated annealing to four-dimensional error functions in which the sum of the squares of the fourth coordinates is added to the error as an additional restraint, the local minima encountered in reducing the structure to a three-dimensional one which satisfies the distance and chirality constraints can be overcome.^{4,14} At the same time, since atoms in the structure can pass through one another without the four-dimensional distance between them falling below the sum of their hard-sphere radii, the method appears to alleviate the local minimum problem encountered in three-dimensions significantly. Problems with local minima still occur, however, which can only be avoided by careful annealing.

Other, somewhat more analytic, approaches to reducing the dimension without violating the distance constraints are currently being explored. For example, in the *WARP procedure* recently developed by the author, this is done by using the elements of a 3×4 matrix $\mathbf{C}$ as the variables while holding the $4 \times N$ matrix of coordinates $\mathbf{P}$ fixed, thus seeking the minimum of the error function E over all projections and affine transformations:

$$\text{minimize } E(\mathbf{CP}) \quad \text{with respect to } \mathbf{C} \quad (14)$$

This minimization involves only 12 variables, and converges very rapidly. Although the error is only reduced by about a factor of 2 on average, the change in the coordinates can be very large. Thus, this method appears to provide an inexpensive means of improving the coordinates obtained by embedding.

Another extension of the ideas behind the EMBED algorithm is found in the work of Glunt, Hayden and co-workers. These investigators have developed a method, called *modified alternating projections (MAP)*, which reliably locates an $(N - 1)$ -dimensional structure that satisfies arbitrary self-consistent distance bounds.³⁶ This procedure involves repeated diagonalization of an $(N + 1) \times (N + 1)$ matrix, and hence is much more time consuming than EMBED. The MAP procedure, however, constitutes the most powerful general method yet developed for testing distance bounds for consistency, since if the bounds cannot be satisfied by an $(N - 1)$ -dimensional structure, they certainly cannot be satisfied by any three-dimensional structure. If it should prove possible to not only detect, but also isolate, inconsistencies by this method, it may be well worth the computer time required.

In addition, Glunt, Hayden and co-workers have developed an analogous procedure, called the *data box algorithm*, for refining three-dimensional structures versus both distance and chirality constraints.³⁷ This procedure may be summarized as follows:

1. Let $\tilde{\mathbf{D}}_0$ be a matrix of squared trial distances which satisfy the distance limits l_{ij} , u_{ij} (obtained from, for example, triangle bound smoothing), and use one iteration of MAP to find an $(N - 1)$ -dimensional structure $\mathbf{P}_0$ whose distances are a least-squares fit to $\tilde{\mathbf{D}}_0$.
2. Let $\mathbf{P}_1$ be a three-dimensional projection of $\mathbf{P}_0$, set $\tilde{\mathbf{D}}_1 = \tilde{\mathbf{D}}_0$ and $k = 1$.
3. Use a more efficient version of the majorization algorithm, called the *spectral gradient algorithm*, to obtain coordinates $\mathbf{P}_{k+1}$ whose distances $[d_{ij}] = [\|\mathbf{p}_i - \mathbf{p}_j\|]$ are a weighted least-squares fit to those in $\tilde{\mathbf{D}}_k$, and which minimize suitable chirality restraints.
4. Define $\tilde{\mathbf{D}}_{k+1} = [\tilde{d}_{ij}^2]$ according to

$$\tilde{d}_{ij} = \begin{cases} l_{ij} & \text{if } d_{ij} < l_{ij} \\ u_{ij} & \text{if } d_{ij} > u_{ij} \\ d_{ij} & \text{otherwise} \end{cases} \quad (15)$$

5. If the constraints are satisfied, stop; else set $k = k + 1$ and go to step (3).

With the most recent improvements in the spectral gradient algorithm, the efficiency and reliability of this procedure appears to be roughly comparable to the other methods discussed above.

4 THE CONTRIBUTIONS OF DISTANCE GEOMETRY TO NMR

Distance geometry has not only played an important role in NMR structure determinations, but has also been used to evaluate the efficacy of the geometric information available from NMR. This is done by simulating the constraints that could be obtained from NMR experiments of varying quality and completeness, computing a conformational ensemble for each such set of simulated constraints, and quantifying the precision of these ensembles by, for example, the RMSD (see Section 2.4). In this way, distance geometry has been able to assist NMR spectroscopists in deciding what kinds of experiment are most useful in determining structure, and thereby has played a role in the development of the experimental methodology. In this final section, we highlight some of the contributions of this approach to present-day methods for determining protein structure from NMR.

The original motivation for distance geometry was to develop a formalism for representing the structural information available from a wide variety of experimental and theoretical methods, together with computational methods for determining biomolecular conformation from this information.³⁰ As part of this larger effort, the simulation method described above was used to evaluate the distance constraints available from a number of possible experiments on protein structure, using a simple 'one point per residue' model (which was about all the computers available at that time could handle).³⁸ The most interesting result of this study was that it is better to know many distances imprecisely than it is to know a few distances precisely. In particular, a complete list of all contacts (<1 nm) and noncontacts (>1 nm) present in a globular α -carbon chain was found to be sufficient to determine all its distances to within only 0.1 nm on average. An important implication of these results, which had a substantial influence on subsequent events, is that the information available from the NOESY experiment should be a powerful constraint on the tertiary structure of proteins.

Because the density of constraints available from NOESY at that time was significantly lower than that used in these simulations, and because it was not immediately certain how well the results would extend to more detailed atomic models of proteins, a similar study was later performed using both a more detailed atomic model as well as constraint sets which mimicked those available from a wide variety of solution NMR experiments.³⁹ The conclusions of this latter study not only supported the earlier results, but were actually a good deal better than expected. The reason for this, as is now known, is that a more detailed atomic model enables one to represent the intrinsic rigidity of the polypeptide chain and the steric restrictions on how the interior side chains can be packed together much more accurately than a one-point-per-residue model. The results of this study also enabled us to formulate some general guidelines concerning the optimum strategy for determining a protein structure from NMR data, which may be summarized as follows:

1. In determining the large-scale tertiary structure of a protein's polypeptide backbone, it is much more important to maximize the quantity of interresidue distance constraints than it is to maximize the quality (i.e. precision) of those constraints; sequential, intraresidue and torsion angle constraints play only a secondary role in this regard.

2. In order to determine the 'local' conformation of short segments of the polypeptide chain and their side chains with adequate precision, relatively precise sequential and intraresidue distance constraints are needed; torsion angle constraints derived from coupling constants are also, of course, very useful.

Since stereospecific assignments were not usually available at the time these studies were performed, their effect was not evaluated at that time. Once they became widely available, however, further studies were performed which showed they made a surprisingly strong contribution to the precision, particularly of the local conformation.^{4,8} In part this is due to the elimination of 'pseudoatoms' and the consequent corrections to the distance constraints, but a more significant contribution seems to be due to the directionality information that these assignments provide.

Even though sophisticated refinement methods involving 'back-calculation' of the NOESY cross-peak intensities are coming into use which promise further to enhance the precision of NMR structure determinations,⁴⁰ distance geometry may be expected to continue to play an important role in the overall structure determination process. In the first place, it is a suitable formalism in which to eliminate errors from the data, determine its intrinsic structural implications, and to establish the basic features of the conformation. In the second, since these more complex refinements are ill-conditioned and extremely prone to becoming trapped by local minima, the excellent starting conformations that distance geometry yields are essential if they are to succeed. Finally, whereas these refinements all assume that the solution 'structure' can be adequately summarized by a single conformation, in reality the solution structure is an ensemble of rapidly exchanging conformations. The conformational ensembles that distance geometry yields are therefore a potentially more accurate representation of the solution structure, and in time methods may be developed which enable us to generate or refine these ensembles so as to make them representative of the actual solution ensemble.⁴¹

Several more detailed reviews covering the applications of distance geometry to structure determination by NMR are available.⁴²⁻⁴⁶

1 INTRODUCTION

The introduction of the Hartmann–Hahn¹ technique of cross polarization into solid state nuclear magnetic resonance spectroscopy, particularly when combined with multiple pulse methods² to remove homo- and heteronuclear, dipolar broadening, was a significant addition to the methods available for the study of solid compounds by NMR. When cross polarization and proton decoupling were incorporated into the magic angle spinning technique,³ there was produced a significant enlargement of the repertoire of sensitive NMR spectrometric procedures available for obtaining high-resolution spectra of solid state compounds and materials.⁴ This important new spectroscopic method became known as cross polarization magic angle spinning (CP MAS) NMR. When the ¹³C spectra of compounds containing nitrogen were studied by CP MAS some lines appeared as broadened asymmetric doublets. It was soon realized that this characteristic lineshape resulted from the ¹⁴N nuclear quadrupole moment interfering with the ability of the magic angle spinning to average out the ¹³C–¹⁴N dipolar interactions. This interpretation was based on earlier observations of the ¹³C lineshapes of carbon nuclei bonded to nitrogen in the NMR of single crystals. We shall now briefly describe the main features of such high-resolution NMR spectra of single crystals to provide a suitable background for understanding the theoretical interpretation of the asymmetrical ¹³C–¹⁴N lineshapes in CP MAS spectra.

1.1 Single Crystal NMR Spectra

Within a short time after their introduction, the new NMR spectroscopic techniques were applied to obtain ¹³C chemical shielding data on a wide range of organic compounds. It was soon found in compounds containing a nitrogen nucleus adjacent to the carbon nucleus being studied that splittings

from ¹³C–¹⁴N dipolar couplings were observed. Griffin et al.⁵ found that the NMR spectrum of a single crystal of glycine at a certain orientation with respect to the magnetic field exhibited three lines from the methylene carbons split by adjacent ¹⁴N nuclei. In measurements of the ¹³C chemical shielding tensor in the metal complex K₂Pt(CN)₄Br_{0.3}·3H₂O, Stoll et al.⁶ observed large effects clearly shown to be caused by ¹⁴N quadrupolar interactions. In that compound, the electric quadrupolar interactions are of comparable size to the ¹³C–¹⁴N dipolar interaction; consequently, mixing with the pure Zeeman eigenfunctions occurs. These required eigenfunctions were obtained by the application of first-order perturbation theory and subsequent diagonalization of the combined Zeeman-quadrupole Hamiltonian. Stoll et al. assumed an axially symmetric electric field gradient tensor with its symmetry axis along the C–N bond. Good quantitative agreement was found between the theoretical and experimental spectral lineshapes for all the angular variations studied.

Because amino acids are of great biological importance, the observations of ¹³C–¹⁴N dipolar–quadrupolar interactions clearly meant that single crystal NMR spectra of amino acids would soon be investigated. Thus simultaneously there were reported such detailed studies of alanine⁷ and glycine.⁸ Though these two detailed single crystal studies cover similar ground, we shall give details about the more complete studies of alanine and use some of the theoretical ideas later in our discussion of the effects of ¹⁴N quadrupolar interactions causing asymmetry in certain magic angle spectral lineshapes of compounds with C–N bonds.

The proton-enhanced proton-decoupled ¹³C NMR spectra of a single crystal of L-alanine were studied by Naito et al.⁷ The C-α line showed a triplet pattern arising from dipolar coupling with the ¹⁴N (*S* = 1) nuclei (Figure 1). These splittings were asymmetric, especially in the *a*-axis orientation. The dipolar interactions in the presence of the ¹⁴N quadrupolar interaction were calculated by applying ideas first employed by VanderHart et al.⁹ to provide a theoretical analysis of the static proton resonance spectra of polycrystalline HMn(CO)₅ and HCo(CO)₄. The appropriate Hamiltonian for the case where the quadrupole asymmetry parameter *η* is zero is written in the following form for later convenience:

$$\mathcal{H} = -\gamma_N \hbar B_0 S_z + \frac{\chi \hbar}{4S(2S-1)} [3S_z^2 \cos^2 \theta + 3S_x^2 \sin^2 \theta + 3(S_z S_x + S_x S_z) \sin \theta \cos \theta - S^2] \quad (1)$$

where the quadrupolar coupling constant is $\chi = e^2 q Q / h$. This Hamiltonian was used to determine the required eigenfunctions of the ¹⁴N nucleus, and these in turn employed to calculate the eigenfunctions of the ¹³C–¹⁴N dipolar interaction as a function of *θ*, the angle between the direction of the external magnetic field and the symmetry axis of the electric field gradient tensor, i.e., the C_θ–N bond direction. It was thus possible to calculate the three ¹³C resonances predicted (and observed experimentally for the C-α nucleus) which correspond to the nitrogen Zeeman states | + 1⟩, | 0⟩, and | − 1⟩, respectively. When the sign of the quadrupole coupling constant was assumed to be positive, good agreement was found between the calculated and experimental data for all the angles studied. The experimental results thus give the sign of the quadrupole coupling constant.

2 MAGIC ANGLE SPINNING

As is well known, MAS tends to average out anisotropic interactions to their corresponding isotropic values when they are very weak as compared with their Zeeman interactions. Theoretical consideration of the effect of the ^{14}N quadrupolar interaction on the ^{13}C MAS spectra based on the above ideas, show that for ^{13}C nuclei bonded to ^{14}N an asymmetric doublet pattern is expected. Lippmaa et al.¹⁰ reported that a high-resolution rotational-synchronized proton-enhanced magic angle spinning ^{13}C NMR spectrum of the polycrystalline solid of the one-dimensional compound tetrathiofulvalene-tetracyanoquinodimethane (TTF-TCNQ) exhibited a three-line spectrum, one line of which consisted of an asymmetric doublet which they attributed to the C-N group. The splitting was found to be field-dependent and identified as arising from dipole-dipole interaction with the ^{14}N nuclei having a quadrupole interaction of comparable magnitude to their Zeeman interaction. This was the first observation of an asymmetric lineshape in a ^{13}C magic angle spinning NMR spectrum of a compound containing a ^{13}C - ^{14}N bond.

3 EFFECTS OF AN AXIALLY SYMMETRIC ELECTRIC FIELD GRADIENT

The influence of spinning on the solid state NMR spectrum of a molecular system consisting of spin pairs in which one of the two spins has a quadrupole moment was first treated theoretically by Kundla and Alla.¹¹ The quadrupolar interaction fixes the spin moment at a definite orientation in the principal axis system (PAS) of the molecule. Rotation of the sample causes a rotational synchronized movement of the spin moment which does not permit the complete averaging of the dipole-dipole interaction between the spin- $\frac{1}{2}$ nucleus I and the quadrupole nucleus $S = 1$. The degree of the averaging depends on the ratio of the quadrupolar and Zeeman energies of the S nucleus.

The Hamiltonian may be written as

$$\mathcal{H} = \mathcal{H}_Z^I + \mathcal{H}^S + \mathcal{H}_D^{IS} \quad (2)$$

Here $\hat{\mathcal{H}}_Z^I$ is the Zeeman term of the I nucleus, $\mathcal{H}^S$ is the quadrupolar Hamiltonian, and $\mathcal{H}_D^{IS}$ the dipolar interaction

Hamiltonian between the I and S spins. It is assumed that $\mathcal{H}_D^{IS}$ is small so that first-order perturbation theory may be applied to calculate the resonance frequencies of the I -spin spectral lines. Because of the rotation of the sample at frequency ω_r , the eigenfunctions and eigenvalues of the unperturbed system become time-dependent. These were calculated for the case where the quadrupole coupling is symmetric. The energy levels were expressed in terms of parameters such as $k = \omega_Q/\omega_Z^S$; θ , the angle between the rotation axis and the magnetic field; the Euler angles α , β , and γ of the sample-fixed coordinate system, in which the α axis coincided with the rotational axis; and the PAS. When $\theta = 0$, the eigenvalue equations became the same as those giving the dependences of the spectral lines on the orientation of the nonrotating single crystal as described by Stoll et al.⁶ To obtain the lineshapes and resonances of the polycrystalline sample at high spinning speeds, the average positions, $\overline{\Delta_n^D}$, were obtained by averaging over all orientations represented by the angle β . Numerical calculations for the magic angle case showed that the line splittings and total widths depend strongly on the relative strengths of the Zeeman and quadrupolar interactions. Moreover, it was shown that in a strong magnetic field, the I -spin spectrum is an asymmetric doublet, one of the lines being the sum of two components, the full width of the single line being twice as large as that of the composite line. The splitting increased with increasing k leading to a regular triplet. The isotropic spin-spin interaction between the I and S nuclei was predicted to shift the I -spin spectral lines, the effect decreasing with increasing values of k .

Apparently unaware of the above work of the Estonian scientists, several groups reported CP MAS spectra of polycrystalline organic compounds containing C-N bonds such as amino acids, peptides, and proteins in which significant differences were observed between the solid state spectra and those in solution.^{12,13} Most of the resonances from carbons bonded to nitrogens were split into broadened doublets, and some of the resonances from more distant carbons were also affected.

A classical and much studied example is the CP MAS spectrum of polycrystalline alanine.¹⁴ The observed splittings of the asymmetric doublet of the C- α resonance was 45 Hz with a 200 MHz magnet and ~ 100 Hz when measured at 90 MHz. The spectra can be fully interpreted and quantitatively explained by the following theoretical treatment.¹⁴ First, the ^{14}N quadrupolar interaction is of comparable magnitude to the Zeeman interaction, so the ^{14}N spin eigenfunctions must be determined by diagonalizing the nitrogen Zeeman quadrupole Hamiltonian, and those eigenfunctions used in the calculation of the ^{13}C - ^{14}N dipolar interactions. At the outset it should be understood that in this problem it is important to be mindful of the timescale of the magic angle spinning. In the experiments described by Naito et al.¹⁴ the spinning frequency was 4.5 kHz, which is small compared with the ^{14}N quadrupolar interaction in L-alanine for which $\chi = 1.205$ MHz; the adiabatic approximation can therefore be employed to determine the nitrogen spin functions at time t from the following equation

$$\mathcal{H}_{ZQ}\psi_N(t) = E(t)\psi_N(t) \quad (3)$$

Here, $\mathcal{H}_{ZQ}(t)$ is the Zeeman quadrupole Hamiltonian of the nitrogen nuclei at time t . For the amino nitrogen in amino

acids and the cyano nitrogen in nitriles, one may assume with a high degree of accuracy that the electric field gradient tensor is axially symmetric, i.e., $\eta = 0$. Thus for the MAS spectrum of L-alanine we can write the Zeeman quadrupole Hamiltonian as

$$\begin{aligned} \mathcal{H}_{ZQ}(t) = & -\gamma_N \hbar S_z B_0 + \frac{\chi \hbar}{4S(2S-1)} [3S_z^2 \cos^2 \theta(t) \\ & + 3S_x^2 \sin^2 \theta(t) + 3(S_z S_x + S_x S_z) \sin \theta(t) \\ & \times \cos \theta(t) - S^2] \end{aligned} \quad (4)$$

Here, $\theta(t)$ is the periodic value of the angle between the field direction $\mathbf{B}_0$ and the internuclear vector $\mathbf{r}_{CN}$. Under MAS, when a rigid array of nuclei is rotated with an angular velocity ω_r about an axis inclined at an angle β to the direction of the external magnetic field $\mathbf{B}_0$, and at an angle β' to $\mathbf{r}_{CN}$, we may write that $\theta(t)$ can vary as follows:

$$\cos \theta(t) = \cos \beta \cos \beta' + \sin \beta \sin \beta' \cos(\omega t + \psi) \quad (5)$$

where ψ is the azimuthal angle of $\mathbf{r}_{CN}$ at time $t = 0$.

In this case the ^{13}C - ^{14}N dipolar interaction is very small compared with the Zeeman interaction, so first-order perturbation theory can be used to calculate the ^{13}C - ^{14}N dipolar interaction at time t . The dipolar splitting of the ^{13}C resonance resulting from that calculation using the Hamiltonian $\mathcal{H}_{ZQ}$ represented by equation (3) yields

$$\begin{aligned} \Delta E_i(t) = & -\gamma_C \gamma_N \hbar^2 / r_{CN}^3 \{ [a_i(t)^2 - c_i(t)^2] [1 - 3 \cos^2 \theta(t)] \\ & - (9/2)^{1/2} [a_i(t) + c_i(t)] b_i(t) \sin 2\theta(t) \} \end{aligned} \quad (6)$$

Here, $a_i(t)$, $b_i(t)$, and $c_i(t)$ ($i = 1, 2$, and 3) are the coefficients at time t of the Zeeman quantized spin functions of the nitrogen nuclei, namely, $|1\rangle$, $|0\rangle$, and $|-1\rangle$, respectively. In L-alanine the ^{13}C - ^{14}N dipolar interaction, 0.6636 kHz, is small compared with the spinning frequency 4.5 kHz, so in such cases the $\Delta E_i(t)$ have to be averaged from $t = 0$ to $t = \infty$ to obtain the ^{13}C - ^{14}N dipolar energy of the spinning sample. The values of $\Delta E_i(t)$ were calculated for each 5° of $\omega t + \psi$ in the range 0° to 360° with constant β' , and these values were then averaged to yield $\overline{\Delta E_{i\beta'}(t)}$. The theoretical lineshapes for polycrystalline samples rotating at the magic angle $\beta = 54.7^\circ$ are obtained by calculating the numerical values of $\overline{\Delta E_{i\beta'}(t)}$ when β' is varied in steps of 2° in the interval 0° to 90° , each $\overline{\Delta E_{i\beta'}(t)}$ being weighted by its probability $\sin \beta'$. Finally, convoluting the theoretical lineshapes with a Gaussian function gave the actual lineshape. The linewidth of the Gaussian function is an adjustable parameter which takes into account any instrumental line broadening, such as effects arising from improper decoupling setting, any slight misalignment of the magic angle, and any magnetic field inhomogeneities, etc.

As shown in Figure 1, the calculated and experimental spectra agreed well. Clearly the calculated lineshape is an asymmetric doublet with a splitting of 48 Hz for a ^{13}C resonance frequency of 50.3 MHz and 108 Hz for a resonance frequency of 22.6 MHz, both values in good agreement with experimental observations.^{12,14} This field-dependence of the asymmetric doublet splitting arises because a weak field causes a relative increase in the contributions from the off-diagonal elements of the matrix representation of the Hamiltonian

$\hat{\mathcal{H}}_{ZQ}(t)$. Noteworthy also was the finding that when the sign of the term $\chi \hbar$ in the lineshape calculation was chosen as negative, the shape was reversed, i.e., the intensity of the high-frequency (low-field) peak was now stronger than the other one. This observation thus presents a means of determining the sign of the quadrupole coupling constant of ^{14}N bonded to ^{13}C by lineshape analysis of the CP MAS ^{13}C NMR spectra.

When the spectrum of cyanoacetamide was studied the same theoretical treatment was applicable because here also the ^{13}C - ^{14}N dipolar interaction, 1.46 kHz, was smaller than the rotor spinning frequency. The lineshape exhibited a reversal of the intensities of the doublet components. When the value of $\chi \hbar$ was taken to be negative, the simulated lineshape was in good agreement with that observed experimentally. The splitting of the asymmetric doublet for the nitrile was 338 Hz in the simulated spectrum, in good agreement with the experimentally measured splittings of 305 Hz to 356 Hz for different cyano compounds.

The above theoretical treatment and the simulated MAS lineshapes were based on the important assumption that the rotor spinning speed was very small in comparison with the size of the quadrupole interaction of the ^{14}N nucleus in the molecule. It was, however, shown that if the spinning speeds were as large as the ^{14}N quadrupolar interaction (i.e., in the MHz range), which seems highly unlikely, the lineshape predicted is quite different from those obtained at low spinning frequencies. For the extremely high spinning frequency case, a truncated Zeeman quadrupole Hamiltonian $\hat{\mathcal{H}}_{ZQ}(t)$ (the time-dependent part is truncated) can be used for the MAS lineshape calculation. Using the same parameters as employed in the simulation of the spectra of nitrile compounds with a value of $\chi = 3.87$ MHz and 24 Hz for the halfwidth of the Gaussian broadening function, it was found that the predicted splitting is less than one-third of the slow-spinning case, giving a broad powder pattern as the expected lineshape.

Contemporaneously with the above work, Zumbulyadis et al.¹⁵ presented an extensive analysis of the influence of quadrupole nuclei on the magic angle spinning spectra of spin- $\frac{1}{2}$ nuclei. Here also, as above, the treatment was restricted to the case with an axially symmetric quadrupolar tensor. The formal theory described was similar to that described above; it also made use of the adiabatic approximation, in which a time-dependent wavefunction is approximated by an eigenfunction of the instantaneous Hamiltonian multiplied by a time-dependent phase factor. Theoretical powder patterns were calculated for a range of values of parameters typical of ^{13}C coupled to ^{14}N , the results being given as a function of ratio of the spin-1 Zeeman frequency Z to the quadrupole coupling constant χ . Each spectrum consisted of double-peaked bands with an intensity ratio of 1:2; the ratio of the S -spin Zeeman to the quadrupolar interaction (Z/χ) determined the widths of the bands and the splittings between them. This was also implicit in the theories of Naito et al.^{14,16} as was the finding that both the widths and splittings of the bands decrease at higher magnetic fields where the quadrupolar interaction induces less mixing of the S -spin Zeeman eigenstates. It was also shown that the appearance of the bands depended critically on the mutual orientations of the unique principal axes of the dipolar and quadrupolar interaction tensors, the doublet splitting going through a minimum when the two principal axes were oriented at the magic angle *with respect to each other*.

4 ¹⁴N EFFECTS OF AN ASYMMETRIC ELECTRIC FIELD GRADIENT

Though the above theoretical treatments^{14,15} were successful in providing an interpretation of the CP MAS ¹³C spectra of a number of nitrogen-containing compounds and, in particular, explaining the asymmetric lineshapes associated with C–N bonds, the restriction to cases with symmetric ¹⁴N quadrupolar tensors was limiting. When the quadrupole coupling parameter $\eta \neq 0$, the C–N bond direction may not be parallel to the principal axis of the quadrupolar tensor. In this situation the off-diagonal elements in the matrix representation of the Hamiltonian $\mathcal{H}_{ZQ}$ will contain η , and hence a large value of the quadrupolar asymmetry parameter will be quite effective in determining the resulting MAS lineshape.

To extend the theory to include the ¹³C CP MAS spectra of important organic molecules such as nitroanilines, and biomolecules like imidazoles, polypeptides, and proteins in which the influence of asymmetry of the ¹⁴N quadrupole coupling tensor may play an important role in determining the lineshapes of the spectra, it was necessary to extend the theoretical formulation though the basic ideas were still sufficient to permit the required extension to encompass a wider range of molecular environments.¹⁶

The adiabatic approximation represented by equation (2) is still used but the Zeeman quadrupole Hamiltonian for ¹⁴N must be modified to reflect the asymmetry of η , the nitrogen asymmetry parameter. The Hamiltonian is now written as

$$\mathcal{H}_{ZQ}(t) = -\gamma_N \hbar B_0 S_z' + \frac{eQq_{zz}}{4S(2S-1)} \times \{(3S_z'^2(t) - S^2) + \eta[S_x'^2(t) - S_y'^2(t)]\} \quad (7)$$

where $\eta = (q_{xx} - q_{yy})/q_{zz}$; eq_{ii} are the principal values of the electric field gradient tensor at the ¹⁴N nucleus in the compound. They obey the convention that $|q_{zz}| \geq |q_{yy}| \geq |q_{xx}|$. The quantity e^2Qq_{ii} ($i = x, y, z$) is one of the principal values of the quadrupole coupling tensor and e^2Qq_{zz} is the quadrupole coupling constant. In this case there are two different coordinate systems to be considered. The Zeeman coordinate system is specified by (x', y', z') , and the principal axis system coordinates of the ¹⁴N electric field gradient tensor of the compound by (x, y, z) . The Euler angles of the spinner rotation axes (x^R, y^R, z^R) are written as β' , θ , and ψ . The magic angle spinning axis, z^R , is inclined at an angle β' with the z axis, and at the magic angle β to the static magnetic field (Z'). The angle ψ is time-dependent and given by $\psi = \omega_r t + \psi_0$, where ψ_0 is the initial angle when $t = 0$ and ω_r is the angular velocity of spinning. Transformations of the coordinate systems (see Figure 2) give the ¹⁴N Zeeman quadrupole Hamiltonian in the Zeeman coordinate system, and the resulting eigenstates are used to calculate the ¹³C–¹⁴N dipolar energy. Since, in general, the internuclear vector r_{CN} is not collinear with the z axis of the electric field gradient tensor, its direction is defined by the polar angles (θ, ψ) in the principal axis system of the electric field gradient tensor. First order perturbation theory can again be used to calculate the ¹³C–¹⁴N dipolar energy of the ¹³C resonance of a certain

Figure 2 Diagrammatic representation of the coordinate transformations required to calculate the ¹³C lineshapes when the quadrupolar parameter η is asymmetric. They can be summarized as follows:

$$\begin{array}{ccccc} x, y, z & & x^R, y^R, z^R & & x', y', z' \\ \text{Principal} & \xrightarrow{(\beta', \phi, \psi)} & \text{Rotating} & \xrightarrow{(\beta, 0, 0)} & \text{Zeeman} \\ \text{axis system} & & \text{axis system} & & \text{axis system} \end{array}$$

molecular orientation at time t and is given by

$$\Delta E_{i\beta'\Phi}(t) = \langle \beta | \psi_N(t) | \mathcal{H}_D(t) | \beta \rangle \psi_N(t) - \langle \alpha | \psi_N(t) | \mathcal{H}_D(t) | \alpha \rangle \psi_N(t) \quad (8)$$

Here, $|\alpha\rangle$ and $|\beta\rangle$ are the ¹³C Zeeman spin functions. As before, the ¹³C–¹⁴N dipolar interaction is smaller than the spinning frequency, so $\Delta E_{i\beta'\Phi}(t)$ must be averaged over one rotor cycle, i.e., from $t = 0$ to $t = \infty$, to give the ¹³C–¹⁴N dipolar energy in the spinning sample, namely

$$\overline{\Delta E_{i\beta'\Phi}(t)} = (1/2\pi) \int_0^{2\pi} \Delta E_{i\beta'\Phi}(\psi) d\psi \quad (9)$$

The values of $\overline{\Delta E_{i\beta'\Phi}(t)}$ were calculated numerically for small increments of the appropriate angles and the resulting values averaged. The resulting theoretical averaged line positions for the spinning sample were weighted by their probability, $\sin \beta'$, and then convoluted with a suitable lineshape function to yield the actual lineshape.

One of the first compounds chosen to test the above theory for calculating the MAS lineshapes of molecules containing ¹⁴N nuclei with nonasymmetric quadrupolar tensors, i.e., with $\eta \neq 0$, was polycrystalline 2,6-dimethyl-3-nitroaniline. This molecule has two different types of ¹⁴N nuclei. The ¹³C MAS NMR spectrum showed that the resonances for both the nitro and amino carbon nuclei exhibited asymmetric doublet patterns (Figure 3). The high-frequency line in the nitro doublet was more intense than the other component, whereas the reverse was the case for the amino peak. Clearly the differences in the lineshapes arose from the different signs, orientations, and magnitudes of the respective electric field gradient tensors for the two ¹⁴N nuclei. Calculations of the theoretical lineshapes by the method outlined above using the appropriate molecular parameters and a reasonable assignment for the orientation of the ¹⁴N electric field gradient tensor based on that of *p*-nitrotoluene yielded lineshapes similar to those observed

Figure 3 Lineshape of the resonance of the carbon nucleus adjacent to the NO₂ group in the ¹³C CP MAS spectrum of 2,6-dimethyl-3-nitroaniline. Computer-simulated spectrum calculated with a quadrupolar asymmetry parameter $\eta = 0.408$ and (a) the ¹⁴N quadrupolar coupling constant $e^2Qq_{zz}/h = -1.340$ MHz; (b) the quadrupolar coupling assumed to be positive. (Reproduced by permission of Academic Press from Naito et al.¹⁶)

experimentally. With the value of χ being 1.340 MHz and $\eta = 0.408$ for ¹⁴N of the -NO₂ group, good agreement was found with the experimental lineshape only when the sign of the quadrupole coupling constant was taken as negative. The simulation of the lineshape of the amino peak required more insight. Values for χ , η , and $\gamma_C\gamma_N\hbar/(2\pi r_{CN}^3)$, based on literature information, were chosen to be 3.977 MHz, 0.263, and 0.8466 kHz, respectively. In the case where the z axis of the quadrupole coupling constant was chosen to lie normal to the plane of the NH₂ group and the y axis assumed to be tilted 40° from the C-N bond direction, with the sign of the quadrupole coupling constant negative the resulting simulated lineshape was in excellent agreement with that observed experimentally. Also, the calculated value for the doublet splitting was 110 Hz, in good agreement with the observed value of 102 Hz.

It proved more difficult to provide an unambiguous interpretation of the lineshapes of the ¹³C CP MAS NMR spectrum of polycrystalline glycylglycine and glycyl-L-alanine. Here again the orientation of the principal axes of the ¹⁴N quadrupole coupling tensor was unknown. Proceeding as before, the calculated lineshapes for the case where the z axis was assumed to lie along the direction of the N-H bond led to a narrow singlet pattern not in agreement with the experimental spectrum. When the z axis was chosen to be normal to the C-N-C plane and the y axis along the N-H bond, the simulated lineshapes again did not agree with the observed lineshape. Several possible orientations of the axes were tried, but only when the z axis of the quadrupole tensor of the amino nitrogen was assumed to lie along the C-N bond direction and the sign of the quadrupole coupling constant taken as positive, together with acceptable values of the other constants, was a satisfactory lineshape simulation obtained. Moreover, the calculated doublet splitting for the C- α carbon in glycylglycine was 49 Hz, which was in good agreement with the experimental value of 41 Hz.

Given the satisfactory simulations of the observed lineshapes from the theory for amino acids and polypeptides, attention was then turned to a more sophisticated molecule of biological interest, namely, trimethylimidazole. This molecule

has two different types of nitrogen nuclei. The quadrupole coupling constants and asymmetry constants of the two nitrogen nuclei are for N-1, $\chi = 1.424$ MHz and $\eta = 0.980$, and for N-2 $\chi = 3.267$ MHz and $\eta = 0.129$. The large difference in the two quadrupolar tensors for the two nitrogen nuclei is obviously mainly the cause of the notable difference between the lineshapes observed for the C-4 and C-5 carbon atoms in the CP MAS spectrum of ¹³C in this compound. Nevertheless, it was only possibly to simulate the experimental lineshapes successfully after a judicious choice of the orientations with respect to the molecular axes of the respective quadrupolar tensor axes.

Furthermore, this work clearly showed that in nitrogen-containing organic compounds, if the correct quadrupole coupling tensor and the relative orientations of the principal axes with respect to the molecular axes are known for a particular nitrogen nucleus, it is possible to calculate the theoretical lineshape for the carbon nucleus bonded to the nitrogen. That the sign of the quadrupole coupling constant for the nitro and amino nitrogen atom in organic compounds differed was new. Since each group containing a nitrogen atom has a characteristic quadrupole coupling tensor, it follows that the ¹³C resonances in the CP MAS NMR spectra of the carbon atoms in such groups, e.g., -NO₂, -NH₂, $\equiv$ N, -NH₃⁺, and -CN, all exhibit characteristic lineshapes. This information is obviously of considerable practical importance for the assignment of the solid state ¹³C CP NMR spectra of organic compounds, particularly those of biological importance and heterocyclic compounds, pharmaceuticals, dyestuffs, etc.

Another approach to calculating the lineshapes of the ¹³C MAS spectra of nitrogen-containing organic compounds was put forward by Hexem et al.¹⁷ This was based on writing the Hamiltonian of the spin system in terms of irreducible spherical tensor operators, namely

$$\mathcal{H} = \sum_{\lambda} \sum_l \sum_{m=-l}^l (-1)^m R_{l-m}^{\lambda} T_{lm}^{\lambda} \quad (10)$$

In this equation, λ represents the type of interaction, including the Zeeman interactions for the carbon, Z_C , and nitrogen spins, Z_N ; the quadrupole interaction of the nitrogen spin, Q ; D , the ¹³C-¹⁴N dipolar interaction; and CS , the chemical shielding of the carbon spins. The quantity J , the indirect spin-spin interaction, is ignored because it was assumed to be negligible. The rotational properties of the irreducible spherical tensors were used to obtain the Hamiltonian in a more convenient form. The time-dependence of the resulting Hamiltonian was removed by applying average Hamiltonian theory. The part of the average Hamiltonian representing the dominant interactions of the carbon atoms and which commutes with the appropriate Zeeman Hamiltonian can be written as

$$\begin{aligned} \mathcal{H}^C(\phi) = & C^Z \rho_{00}^Z T_{00}^Z + C^{CS} \rho_{00}^{CS} T_{00}^{CS} \\ & + \sum_{m=-2}^2 C^D (-1)^m R_2^D - (\phi) T^D 3_{2m} \end{aligned} \quad (11)$$

where $C^Z = \gamma_C \hbar$, $C^{CS} = \gamma_C$, $\rho_{00}^{CS} = \sigma_{iso}$, $T_{00}^Z = B_{00} I_z$, $C^D = -2\gamma_C\gamma_N\hbar^2$, and σ_{iso} is the isotropic chemical shift. Making use of Wigner rotation matrices, one set of Euler angles transforms the principal axis system of the dipolar interaction

to the principal axis system of the electric field tensor, while the angles $(0, \theta_M, \psi)$ transforms further the spatial components to the axis system of the spinning rotor. In this last transformation, θ_M is the magic angle (54.7°) and ψ is the azimuthal angle of rotation about the rotor axis.

The shifts in the energy levels of ^{13}C were calculated using zero-order average Hamiltonian theory, which is equivalent to first-order perturbation theory, this procedure being possible because the small size of the dipolar coupling means that it can be treated as a perturbation. Because of the relative orders of magnitude of the ^{14}N quadrupole coupling constant and the lower achievable spinning rates, one cannot use zero-order average Hamiltonian theory to average $\hat{\mathcal{H}}_{\text{CN}}^{\text{D}}$, the heteronuclear Hamiltonian over one rotational period. The ^{14}N matrix was diagonalized and the induced carbon shifts calculated. The carbon shifts were calculated for a sufficient number of points as described in the earlier theoretical treatments. These dipolar shifts were averaged over one rotation period $\overline{\omega_n^{\text{C}}}$ by numerical integration over the azimuthal angle of rotation, ϕ . This is equivalent to assuming the adiabatic approximation for calculating the change of the nitrogen states over the rotational period described in detail earlier by Naito et al.^{14,16} and by Zumbulyadis et al.¹⁵

As a preliminary test of theory, and to compare the results from diagonalizing the nitrogen Hamiltonian matrix with those obtained by using first-order perturbation theory to obtain the coefficients in the eigenfunction $\Phi_n^{\text{N}}(\phi)$ representing a linear combination of the Zeeman spin states, Hexem et al.¹⁷ calculated the expected powder ^{13}C spectrum for a C–N bond. Typical values of the parameters were used and the quadrupole coupling tensor was assumed to be axially symmetric with $\eta = 0$. When these theoretical predictions for the lineshapes were compared with the experimental observations for polycrystalline alanine, it was clear that the spectra lacked the resolution to show the fine structure predicted by the powder pattern. The calculated spectrum obtained using a value of 0.26 for the quadrupole asymmetry parameter, η , and taking its sign as positive was in good agreement with the experimental spectrum, in general accord with the findings of Naito et al.¹⁶

Explaining the ^{13}C lineshape of the α -carbon in *N*-acetylvaline was more challenging. In this case $\eta = 0.31$ and in the case of the polypeptide bond study of Naito et al.¹⁶ it was necessary to consider carefully the relative orientations of the principal axes of the electric field gradient tensor with respect to the molecular axes. Consideration of several orientations soon yielded a set of parameters which produced good agreement between the computer simulated lineshape and that observed experimentally.

The extensive studies of Hexem et al.¹⁷ and Naito et al.¹⁶ showed clearly that comparing the experimental and computer-calculated spectra provides a ready method for obtaining information concerning the relative orientations of the dipolar and electric field gradient tensors from the manifestations of the influences of those parameters on the ^{13}C NMR lineshapes. Moreover, such studies also enable the sign of the asymmetry parameter of the ^{14}N nucleus bonded to the carbon to be established. Also, as is clearly apparent from the theoretical treatments outlined earlier in this article, the extent of the splitting between the doublet peaks characteristic of the ^{13}C resonance of a C–N bond depends on the magnitude and the asymmetry parameter of the ^{14}N quadrupole tensor, the

internuclear distance, the strength of the applied magnetic field, and the orientation of the internuclear vector r_{CN} in the principal axis system of the electric field gradient tensor.¹⁸

Kundla and Alla¹¹ had earlier shown that the line splittings and total widths depended on the relative strengths of the Zeeman and quadrupolar interactions. The magnitude of the splitting is directly dependent on the dipolar interaction and the asymmetry parameter, which is different for differing values of the Euler angles defining its spatial orientation, with the Zeeman frequency of the ^{14}N nucleus being Z_{N} , the dipolar coupling $D = \gamma_{\text{C}}\gamma_{\text{N}}\hbar/4\pi^2 r_{\text{CN}}^3$, and the polar and azimuthal angles as β^{D} and α^{D} , the doublet splitting S is given by:

$$S = \frac{9}{20}(D\chi/Z_{\text{N}})(3\cos^2\beta^{\text{D}} - 1 + \eta\sin^2\beta^{\text{D}}\cos 2\alpha^{\text{D}}) \quad (12)$$

which is in terms of all the geometric ($r, \alpha^{\text{D}}, \beta^{\text{D}}$) and energy variables (χ, Z_{N}, η) up to first order in (χ/Z_{N}) . As a test of equation (13) the values of the splitting S predicted by that equation were plotted against the experimentally observed splittings for more than 20 compounds containing different types of C–N bonds.¹⁹ An excellent linear relationship was found which may, at first sight, seem surprising because of the wide range of different molecular species involved.

5 INFLUENCE OF J COUPLING

In the Hamiltonians used in all the theoretical treatments described, the term $\mathcal{H}_J$ representing the indirect J coupling was ignored. This was because the value of J_{iso} was expected to be so small that it would have little, or no effect, on the CP MAS lineshapes of ^{13}C – ^{14}N -containing compounds. The excellent agreements found between the experimental and theoretical lineshapes shows that this was usually an easily justifiable assumption. The inclusion of J coupling leads to the introduction of the term:²⁰

$$[-(\Delta J/3)(3\cos^2\beta^J - 1 + \eta\sin^2\beta^J\cos 2\alpha^J)] \quad (13)$$

where β^J and α^J give the orientation of the unique z axis of the $\mathbf{J}$ tensor in the PAS of the quadrupole tensor. To illustrate the effect of the J coupling, Figure 4 shows how the normal two-peak powder spectrum becomes a three-peak spectrum for the case of ^{14}N . The theoretical spectra were calculated from the computer program of Naito et al.,^{14,16} modified to include the term $\mathcal{H}_J$ in the Hamiltonian. The introduction of the indirect spin–spin coupling results in a splitting of the $m_{14\text{N}} = -1$ and $+1$ levels, while the $m_{14\text{N}} = 0$ peak is unaffected. In the calculations, the ^{14}N electric field gradient tensor was assumed to be axially symmetric with the largest principal component parallel to the ^{13}C – ^{14}N dipolar vector. A similar procedure was employed by Eichele and Wasylishen,²¹ though they used a different computer program based on the perturbation method to interpret and simulate the spectrum demonstrating the first observation of the indirect spin–spin coupling $^1J(^{14}\text{N}, ^{13}\text{C})$ effect which they discovered in the ^{13}C CP MAS NMR spectrum of $[(n\text{-C}_3\text{H}_7)_4\text{N}][\text{Cd}(\text{SCN})_3]$. Because of the excellent agreement found between the simulated and the experimental spectra they estimated the value of $^1J(^{14}\text{N}, ^{13}\text{C}) = 11 \pm 3$ Hz.

Figure 4 Diagrammatic representation of the effect of including the term $\mathcal{H}_J$ in the Hamiltonian before calculating the lineshape

6 OTHER SPIN- $\frac{1}{2}$ NUCLEI BONDED TO ^{14}N : ^1H CRAMPS

Protons are ubiquitous in nature and bond to many different types of nuclei. Of these the bonding to ^{14}N is important because N–H bonds are fundamental in the molecular composition of amino acids, polypeptides, and proteins. Unfortunately, the ^1H CP MAS spectra of such compounds were generally found to be lacking in structure because of the dipolar broadening caused by homonuclear interactions and magnetic shielding anisotropies. The introduction of the technique of combining sample rotation and multiple pulse NMR spectroscopy, the so-called CRAMPS procedure pioneered by Gerstein et al.,²² was a major innovative addition to the CP MAS methodology which considerably enlarged its range of applications, making it possible to obtain high-resolution proton spectra of hydrogen-containing solids many of which are of great industrial importance. When applied to solid amino acids the CRAMPS technique yielded proton CP MAS spectra in which there were identified²³ asymmetric peaks clearly arising from the ^1H – ^{14}N dipolar interaction and the ^{14}N quadrupole interaction not being averaged out, as earlier described for the analogous ^{13}C – ^{14}N case. The resolution of the characteristic asymmetric lineshapes varied with the type of multiple pulse sequence used. This was presumably because a faster spinning frequency was required to reduce the N–H dipolar interactions. In all cases, characteristic asymmetric doublets were observed for the ^1H – ^{14}N bonds, with the exception of the N-2 and N-3 nuclei in the imidazole ring of L-histidine hydrochloride monohydrate. Those two bonds exhibited broad asymmetric peaks, possibly being the result of strong hydrogen bonding.

The asymmetric peaks in the CRAMPS MAS spectra of amino acids were simulated by Naito et al.²³ using the computer programs based on the theoretical treatments

Figure 5 Lineshape of the CP MAS spectrum of a proton bonded to the peptide nitrogen nucleus in *N*-acetyl glycine. (a) Experimental spectrum obtained by using CRAMPS with the MREV-8 pulse sequence. (b) Computer-simulated spectrum obtained using a quadrupolar asymmetry parameter $\eta = 0.32$ and $e^2Qq_{zz}/h = -3.21$ MHz. (Reproduced by permission of the American Chemical Society from Naito et al.²³)

described earlier.^{14,16} In addition, it was necessary to multiply the quadrupole and Zeeman terms in the Hamiltonian by the scaling factors $S_m S_r$. The term S_m is the scaling factor for the multiple pulse scheme used, and $S_r = \frac{1}{2}(3 \cos^2 \theta - 1)$ is the scaling factor caused by a group rotation where θ is the angle between the rotation axis and the N–H direction. The lineshapes were simulated successfully. That of the peptide proton was well simulated (see Figure 5) using the ^{14}N coupling constant of -3.2 MHz and $\eta = 0.31$, the parameters having been determined in a single crystal ^{14}N NMR study on *N*-acetylvaline though the sign of the quadrupole coupling constant had been established previously from a comparison of the experimental and computer-simulated peptide carbon nuclei.¹⁶ In addition, it was necessary to interchange the assigned axes of the electric field gradient tensor so that the x axis was parallel to the N–H bond direction. The spectral peaks for the proton bonded to the imidazole nitrogen N nuclei were simulated using the ^{14}N coupling constants earlier determined from ^{14}N NMR single crystal studies. The simulated spectra showed that broad lines were to be expected and that a clear asymmetric doublet was not to be anticipated in this case. It was also to be expected that the proton bonded to the N-2 nucleus should have a broader lineshape than that for the N-3 nucleus. These predicted lineshapes were in good agreement with those observed experimentally.

The interesting ^{14}N -containing spin-pairs $^{14}\text{N} \equiv ^{15}\text{N}^+ -$ and $^{15}\text{N} \equiv ^{14}\text{N}^+ -$ yield unusual lineshapes.²⁴ It should also be mentioned that the ^{13}C MAS lineshapes of the parent compounds 5-methyl-2- $[\alpha\text{-}^{15}\text{N}]$ diazobenzenesulfonic acid and its isotopomer with $[\beta\text{-}^{15}\text{N}]$ exhibit characteristic novel lineshapes. It was, however, possible to obtain approximate lineshape simulations for the ^{13}C – ^{14}N residual dipolar couplings even though the resulting ragged appearances of the simulations were clearly caused by the use of insufficient increments of the orientations of the angles β^Q and γ^Q in the calculations. Convolution of the two simulated spectra yielded a lineshape which was a good reproduction of the spectrum resulting from convoluting the observed ^{13}C MAS spectra of the two isotopomers. An apparent triplet lineshape was observed for the carbon nucleus bonded to the α - and β - ^{14}N nuclei of the diazo group, which arises from two different residual ^{13}C – ^{14}N dipolar couplings acting on the same carbon nucleus. It proved possible to simulate that feature.

Mention should be made of related studies of the lineshapes found for off-magic angle, or variable-angle, ^{13}C NMR spectra of compounds which exhibit ^{13}C – ^{14}N dipolar–quadrupolar interaction effects.²⁵ Though to some extent peripheral to the main thrust of this article, the phenomena described in those studies are of considerable interest.

1 INTRODUCTION

As explained in detail in *Magic Angle Spinning Carbon-13 Lineshapes: Effect of Nitrogen-14*, magic angle spinning does not always eliminate from spin- $\frac{1}{2}$ spectra the influence of dipolar coupling to quadrupolar nuclei. In particular, when quadrupolar energies are not negligible compared with Zeeman energies, spin- $\frac{1}{2}$ spectra may show splittings and/or lineshapes which arise from residual dipolar coupling to quadrupolar nuclei. This phenomenon was first discovered and thoroughly investigated for the (^{13}C , ^{14}N) nuclear pair, but it soon became apparent that the effect was more widespread, indeed ubiquitous. The present article will discuss a wide range of examples and will place particular emphasis on the perturbation approach, which is adequate to explain many cases. The discussion will be limited to the centers of gravity of what are, strictly speaking, powder bandshapes. The reader is referred to *Magic Angle Spinning Carbon-13 Lineshapes: Effect of Nitrogen-14* for details of more exact theory, for questions of powder bandshapes, and for all examples involving ^{14}N . The whole subject has received attention in a review article¹ which summarizes the theoretical approaches and also lists cases for many different nuclear spin pairs.

2 THEORETICAL BACKGROUND

Consider a pair of nuclei I and S , where the former has the spin quantum number $\frac{1}{2}$ and the latter is quadrupolar. For simplicity in this discussion, it will be assumed that the electric field gradient at S is axially symmetric, but the reader must be careful not to infer that the results below apply to the general case of $\mu \neq 0$. The phenomenon mentioned above can be traced to the influence of terms in the quadrupolar Hamiltonian involving nuclear spin operators other than $\hat{S}_z$. When Zeeman terms dominate, the energy levels of quadrupolar nuclei are properly characterised by the spin component quantum number m_S , associated with $\hat{S}_z$. Since the relevant Hamiltonian terms

have angular dependences $\frac{1}{2}(3 \cos^2 \theta_Q - 1)$, where θ_Q is the angle between the major principal axis of the quadrupolar tensor and the applied magnetic field ($\mathbf{B}_0$), their effects are averaged to zero by magic angle spinning at a fast enough rate. Moreover, in such circumstances, the only terms in the dipolar Hamiltonian connecting the quadrupolar nucleus with the spin- $\frac{1}{2}$ nucleus which are secular involve similar angular dependence $\frac{1}{2}(3 \cos^2 \theta_D - 1)$ where θ_D is the angle between $\mathbf{B}_0$ and the internuclear distance between the spin $\frac{1}{2}$ and the quadrupolar nuclei. Thus, magic angle spinning at a sufficiently high rate is enough to eliminate these dipolar interactions. Therefore, resonance frequencies in spin- $\frac{1}{2}$ MAS spectra are unaffected by dipolar interactions to quadrupolar nuclei in such circumstances. Similar considerations apply to anisotropy and asymmetry in the indirect ('scalar') coupling between a spin- $\frac{1}{2}$ nucleus and a quadrupolar nucleus: MAS suffices to remove the influence of such coupling components on the frequencies in the spin- $\frac{1}{2}$ spectrum, though the isotropic part of the coupling is retained.

However, when quadrupolar and Zeeman terms in the Hamiltonian become comparable, the situation is drastically changed. The detailed theoretical treatment using the full Hamiltonian is discussed in *Magic Angle Spinning Carbon-13 Lineshapes: Effect of Nitrogen-14*. Here, the perturbation treatment, which is frequently applicable, will be presented. The use of perturbation theory was pioneered by Olivieri and co-workers² for the (^{13}C , ^{14}N) case (though it was implicit in earlier treatments), and rapidly extended³ to situations involving higher-spin quadrupolar nuclei.

The spin- $\frac{3}{2}$ case is chosen here for illustration purposes. Consider the so-called 'alphabet expansion' of the dipolar and axially-symmetric quadrupolar interactions (Table 1). In the high-field approximation the Zeeman levels may be designated as $|m_S\rangle$, where $m_S = \frac{3}{2}, \frac{1}{2}, -\frac{1}{2}$ or $-\frac{3}{2}$. Under the influence of terms C , D , E , and F of the 'quadrupolar alphabet', these wavefunctions are mixed to become

$$|(-\frac{3}{2})'\rangle = |-\frac{3}{2}\rangle + a_1^* |-\frac{1}{2}\rangle - a_2^* |\frac{1}{2}\rangle \quad (1a)$$

$$|(-\frac{1}{2})'\rangle = -a_1 |-\frac{3}{2}\rangle + |-\frac{1}{2}\rangle + a_3^* |\frac{1}{2}\rangle - a_2^* |\frac{3}{2}\rangle \quad (1b)$$

$$|(\frac{1}{2})'\rangle = a_2 |-\frac{3}{2}\rangle - a_3 |-\frac{1}{2}\rangle + |\frac{1}{2}\rangle - a_1^* |\frac{3}{2}\rangle \quad (1c)$$

$$|(\frac{3}{2})'\rangle = +a_2 |-\frac{1}{2}\rangle + a_1 |\frac{1}{2}\rangle + |\frac{3}{2}\rangle \quad (1d)$$

where, in the perturbation approach, $a_1 = \langle \frac{1}{2} | \hat{\mathcal{H}}_Q | \frac{3}{2} \rangle / \gamma_s \hbar B_0$, $a_2 = \langle -\frac{1}{2} | \hat{\mathcal{H}}_Q | -\frac{3}{2} \rangle / 2\gamma_s \hbar B_0$ and $a_3 = \langle -\frac{1}{2} | \hat{\mathcal{H}}_Q | \frac{1}{2} \rangle / \gamma_s \hbar B_0$, etc.

The alphabet terms C and D are relevant for a_1 and a_3 whereas terms E and F are effective for a_2 . However, it can be shown that $a_3 = 0$ and that a_2 cannot affect the I spectrum. Now, because of the mixed nature of the Zeeman levels, terms C and D of the (I , S) 'dipolar alphabet' become secular, the additional energy contributions being

$$\begin{aligned} \langle (-\frac{3}{2})' m_I | \hat{\mathcal{H}}_D | (-\frac{3}{2})' m_I \rangle &= \langle (\frac{3}{2})' m_I | \hat{\mathcal{H}}_D | (\frac{3}{2})' m_I \rangle \\ &\quad - a_1 D m_I \end{aligned} \quad (2a)$$

$$\begin{aligned} \langle (-\frac{1}{2})' m_I | \hat{\mathcal{H}}_D | (-\frac{1}{2})' m_I \rangle &= \langle (\frac{1}{2})' m_I | \hat{\mathcal{H}}_D | (\frac{1}{2})' m_I \rangle \\ &\quad + a_1 D m_I \end{aligned} \quad (2b)$$

Table 1 The NMR Internal Hamiltonian: The Alphabet Expansion

Term	Geometric factor ^c	Spin factors ^c		
		Dipolar	Quadrupolar ^b	Connectivity
A	$1 - 3 \cos^2 \theta$	$\hat{I}_x \hat{S}_z$	$(\hat{I}_z)^2$	Secular
B	$-\frac{1}{4}(1 - 3 \cos^2 \theta)$	$\hat{I}_+ \hat{S}_- + \hat{I}_- \hat{S}_+$	$\hat{I}_+ \hat{I}_- + \hat{I}_- \hat{I}_+$	Flip-flop ^a
C	$-\frac{3}{2} \sin \theta \cos \theta \exp(-i\phi)$	$\hat{I}_x \hat{S}_+ + \hat{I}_+ \hat{S}_z$	$\hat{I}_z \hat{I}_+ + \hat{I}_+ \hat{I}_z$	Single quantum
D	$-\frac{3}{2} \sin \theta \cos \theta \exp(i\phi)$	$\hat{I}_x \hat{S}_- + \hat{I}_- \hat{S}_z$	$\hat{I}_z \hat{I}_- + \hat{I}_- \hat{I}_z$	
E	$-\frac{3}{4} \sin^2 \theta \exp(-2i\phi)$	$\hat{I}_+ \hat{S}_+$	$(\hat{I}_+)^2$	Double quantum
F	$-\frac{3}{4} \sin^2 \theta \exp(2i\phi)$	$\hat{I}_- \hat{S}_-$	$(\hat{I}_-)^2$	

^aSecular for the quadrupolar and homonuclear dipolar interactions, but nonsecular for heteronuclear dipolar interactions.

^bFor the axially symmetric case ($\eta = 0$).

^cThere are also constant numerical factors ($\hbar D$ for the dipolar case and $\hbar \chi / 2S(2S - 1)$ for the quadrupolar case).

where D is the dipolar coupling constant, $\gamma_I \gamma_S (\mu_0 / 4\pi) (\hbar / 2\pi) r_{IS}^{-3}$ (to be distinguished from the alphabet term D !). Therefore the energy levels are modified as shown in Figure 1, and the outer lines of the I multiplet will be shifted in one direction, while the inner lines will shift to the same extent but in the opposite direction. Of course the terms in the Hamiltonian also involve geometric factors which depend on the Euler angles connecting the dipolar and quadrupolar tensors with the magnetic field $\mathbf{B}_0$. Since these are *not* of the form $(3 \cos^2 \theta - 1)$, they are not eliminated by MAS although they are reduced. Thus each of the multiplet components in the I spectrum will be powder patterns under MAS. However, the structure of these powder patterns is not usually observed, and consequently the useful information normally comes from consideration of the centers of gravity of the bands. Of course the indirect coupling tensor $\mathbf{J}$ has some common features with $\mathbf{D}$, and therefore it will in principle also need to be considered.

Full evaluation for the general case results¹ in the following perturbation expression for the shift induced in the center of gravity of the spin- $\frac{1}{2}$ transition frequency associated with quadrupolar basis state m_S

$${}^2\Delta v(m_S) = \frac{3\chi}{20\nu_S} \left[\frac{S(S+1) - 3m_S^2}{S(2S-1)} \right] \times \left[Df(\alpha^D, \beta^D, \eta) - \frac{\Delta J}{3} f(\alpha^J, \beta^J, \eta) \right] \quad (3)$$

where $f(\alpha, \beta, \eta) = 3 \cos^2 \beta - 1 + \eta \sin^2 \beta \cos 2\alpha$, α and β are the relevant Euler angles (see Harris and Olivieri¹), η is the asymmetry in the electric field gradient, χ is the quadrupole coupling constant, ν_S is the Larmor frequency of the quadrupolar nucleus and ΔJ is the anisotropy in $\mathbf{J}$. The above equation assumes that $\mathbf{J}$ is an axially symmetric tensor. Simplifications result if there are further assumptions. In particular, if $\mathbf{J}$ and $\mathbf{D}$ are co-axial, and if η is ignored, the complete equation for the spin- $\frac{1}{2}$ transition frequency is

$$\nu(m_S) = \nu_I - m_S J_{\text{iso}} + \frac{3D'\chi}{20\nu_S} \left[\frac{S(S+1) - 3m_S^2}{S(2S-1)} \right] \quad (4)$$

where ν_I is the Larmor frequency of the spin- $\frac{1}{2}$ nucleus, J_{iso} is the isotropic part of $\mathbf{J}$, and D' is an effective dipolar coupling constant, incorporating the anisotropy in $\mathbf{J}$

$$D' = D - \frac{\Delta J}{3} \quad (5)$$

The second-order shift itself, $\nu(m_S) - \nu_I + m_S J_{\text{iso}}$, depends only on the square of m_S , and for $m_S = \pm S$ it is independent of S . It is therefore convenient to normalize effects to the shift of the 'outermost' lines, defined as

$$\Delta = -\frac{3}{10} \frac{\chi D'}{\nu_S} \quad (6)$$

This enables the second-order shifts of all lines to be written as

$${}^2\Delta v(m_S) = -\left[\frac{S(S+1) - 3m_S^2}{S(2S-1)} \right] \Delta \quad (7)$$

Table 2 lists the shifts of all lines, for various half-integral values of S , in terms of Δ .

Figure 1 Energy-level diagram for an IS nuclear spin pair with $I = \frac{1}{2}$, $S = \frac{3}{2}$ to show the perturbations induced by quadrupolar and dipolar interactions. The extent of the perturbations is greatly exaggerated. It is assumed that γ_I , γ_S , and J_{iso} are all positive

Table 2 Second-Order Shifts in the Spectra of Spin- $\frac{1}{2}$ Nuclei Arising from Coupling to a Half-Integral Quadrupolar Nucleus S^a

S	m_S				
	$\pm\frac{1}{2}$	$\pm\frac{3}{2}$	$\pm\frac{5}{2}$	$\pm\frac{7}{2}$	$\pm\frac{9}{2}$
$\frac{3}{2}$	-1	1			
$\frac{5}{2}$	$-\frac{4}{3}$	$-\frac{1}{3}$			
$\frac{7}{2}$	$-\frac{5}{2}$	$-\frac{1}{2}$	1		
$\frac{9}{2}$	$-\frac{7}{3}$	$-\frac{1}{3}$	$\frac{1}{3}$	1	
$\frac{11}{2}$	$-\frac{8}{3}$	$-\frac{1}{3}$	$-\frac{1}{6}$	$\frac{1}{3}$	1

^aNote: The values are normalized to the shift of the outermost lines as expressed in equation (6).

3 CONSEQUENCES OF PERTURBATION THEORY

A number of significant features can be understood from equations (3)–(7).

1. While perturbation theory holds, second-order shifts are inversely proportional to B_0 , so that no new information is obtained by using several spectrometers. However, such experiments can be used to check that the origin of splittings in the spectra does indeed involve second-order effects, since the behavior with B_0 differs from that of splittings caused by either J_{iso} or differences in chemical shifts.
2. Since second-order shifts depend on m_S^2 , their values occur in pairs, with the outermost multiplet lines moving most. Figure 2 illustrates the situation as a function of $\chi D/\nu_S$ when $\Delta J = 0$.
3. The average second-order shift is zero, so the isotropic chemical shift is simply obtained by averaging the frequencies of all the lines.
4. The isotropic coupling constant, $|J_{\text{iso}}|$, is also readily obtained as the average spacing between lines, though care must be taken if there is any crossover of frequencies. The value of $|J_{\text{iso}}|$ is also available from the central spacing $|\nu(m_S = \frac{1}{2}) - \nu(m_S = -\frac{1}{2})|$.
5. Since the innermost lines shift in the opposite direction to the effect on the outermost lines, there is a ‘bunching’ of lines at one end of the spectrum. The extent of coalescence is more apparent for lower values of S for a given $\chi D/\nu_S$. The sense depends on the sign of Δ , and in favorable cases it gives important information on relative signs.
6. In particular, if $\mathbf{J}$ and $\mathbf{D}$ are co-axial the following general rule results: ‘bunching’ occurs to low frequency (i.e. Δ is positive) if *either* χ is negative (with D and D' of the same sign) *or* χ is positive (with D and D' of opposite signs). An analogous statement can be made if Δ is negative. This rule takes into account the effects of signs of magnetogyric ratios. Thus, if the magnitude and sign of χ is known, together with r_{IS} , and if η is ignored, then ΔJ can be derived unambiguously. However, if only r_{IS} and $|\chi|$ are available, two possible values of ΔJ can be calculated but they cannot be distinguished.
7. When perturbation theory holds, neither the magnitude nor the sign of J_{iso} influences Δ .
8. If the value of $|J_{\text{iso}}|$ is negligible compared to linewidths, then there will be $S + \frac{1}{2}$ lines. The relative frequencies at which ‘bunching’ takes place will give the sign of χ . The magnitude of Δ will enable r_{IS} to be determined if $|\chi|$ is known, and vice versa. However, $S = \frac{3}{2}$ is a special

Figure 2 Second-order shifts in spin- $\frac{1}{2}$ MAS spectra arising from coupling to a quadrupolar nucleus S , as a function of the parameter $\chi D'/\nu_S$ under a perturbation approach according to equation (7): (a) $S = \frac{5}{2}$; (b) $S = \frac{7}{2}$. A positive value of Δ is assumed

Figure 3 Second-order shifts in spin- $\frac{1}{2}$ MAS spectra arising from coupling to a quadrupolar nucleus $S = \frac{3}{2}$ as a function of the parameter $\chi D'/\nu_S$ under a perturbation approach according to equation (7): (a) $J_{\text{iso}} = 0$; (b) $-J_{\text{iso}} > 0$. A positive value of Δ is assumed

case, since a 1:1 doublet will be seen [Figure 3(a)], of spacing $\frac{3}{10}(\chi D/\nu_S)(3 \cos^2 \beta^D - 1 + \eta \sin^2 \beta^D \cos 2\alpha^D)$ in the general case, and information on the sign of χ is lost.

9. The same denominator in equation (7) reflects the fact that the validity of the perturbation approach depends on $\chi/2S(2S - 1)\nu_S$, higher spins are more accurately treated than lower spins for equivalent values of χ .

4 RESULTS AND DISCUSSION

Many examples are now known where perturbation theory is reasonably applicable. In particular, the (^{119}Sn , $^{35/37}\text{Cl}$) situation is appropriate^{3,4} since in such cases $|\chi|$ is generally modest (~ 35 MHz). Thus even for a 4.7 T spectrometer, the perturbation parameter $\chi/2S(2S - 1)\nu_S$ is only in the region of 0.30. The splitting arising from $|J_{\text{iso}}|$ cannot be ignored. However, since chlorine is monovalent, coaxiality of $\mathbf{J}$ and $\mathbf{D}$ is a reasonable approximation for directly-bonded Sn–Cl groups except when chlorine is in a bridging situation. In fact,

Figure 4 Tin-119 CP MAS NMR spectra at 74.63 MHz for (a) $(\text{PhCH}_2)_3\text{SnCl}$ and (b) Et_2SnCl_2 , showing the second-order effects of coupling to the chlorine nuclei.⁴ The markers are at 1 kHz and 0.5 kHz intervals for (a) and (b), respectively

a typical spectral pattern is a 1:1:2 triplet with relative spacings 2:1 [Figure 4(a)], which is strictly the case only when $|J_{\text{iso}}| = 2\Delta$. Values of $|J(\text{Sn}, \text{Cl})|$ have therefore been derived, as have approximate data for ΔJ . When more than one chlorine is coupled to the same Sn, simple convolution suffices to predict the spectral appearance. If the chlorines are equivalent, then $|J_{\text{iso}}| = 2\Delta$ leads to a 1:2:4:1:4:4 multiplet (with the first spacing twice the others), such as has been observed [Figure 4(b)] for Et_2SnCl_2 .⁴

Cases involving ^{31}P coupled to metal nuclei are also common, and have been shown^{5,6} to occur for a range of S -spin metals, e.g. $^{63/65}\text{Cu}$ ($S = \frac{3}{2}$), ^{55}Mn ($S = \frac{5}{2}$), ^{59}Co ($S = \frac{7}{2}$), and ^{93}Nb ($S = \frac{9}{2}$). Figure 5 shows an example where the second-order effects are relatively small. In a number of such cases perturbation theory is not appropriate, and in others questions of nonaxiality reduce the usefulness of the observed second-order effects. However, the case of $\text{Mn}_2(\text{CO})_9\text{PPh}_3$ proved⁶ to be appropriate, since the molecular symmetry has axiality and spinning sideband analysis indicates that this is retained in the solid state. Such an analysis also gives a value for $|D'|$, so that $|\chi|$ can be derived (42 MHz). The value of $\chi/2S(2S - 1)\nu_S$ for a spectrometer operating at 7.1 T is thus 0.028, which confirms that perturbation theory is applicable. Several (^{31}P , $^{63/65}\text{Cu}$) examples have been analyzed⁷ using perturbation theory to yield data for $\Delta J \sim 0.6$ kHz.

Numerous other examples of residual dipolar coupling have been reported, some of which come into the category of a perturbation treatment. In particular, examples of (^{13}C , ^2H) have been given.^{1,8,9} Although ^2H has a low value of χ , the residual effects of dipolar coupling are appreciable because r_{CH} is small and hence D is relatively large. With rigid molecules,^{1,8} there is a nice contrast to the (^{13}C , ^{14}N) case since, although 2:1 doublets are observed in both instances, the origins differ. For the (^{13}C , ^{14}N) pair J_{iso} can usually be ignored, so there is overlap for the lines connected to states $|+1\rangle$ and $|-1\rangle$ for ^{14}N , whereas for (^{13}C , ^2H), the overlap is of transitions involving $|0\rangle$ and $|-1\rangle$ for ^2H . The latter situation arises coincidentally because $|J_{\text{iso}}(^{13}\text{C}, ^2\text{H})|$ is approximately equal to $\frac{9}{10} D\chi/\nu_S$. The spectra have a different appearance⁹ for inclusion compounds of urea and thiourea with deuterated guest molecules, such as straight-chain alkanes and corresponding carboxylic acids. The guest molecules are relatively mobile, so that values of $\chi(^2\text{H})$ are substantially reduced (to ca. 50–70 kHz for CD_2 groups) by averaging. Second-order effects on the ^{13}C spectra are therefore relatively modest, simply resulting in a small asymmetry in the splittings

Figure 5 Phosphorus-31 CP MAS NMR spectra at 81.0 MHz for $(\text{C}_5\text{H}_5)(\text{Me}_3\text{P})\text{Cl}_2\text{Nb}=\text{N}(o\text{-tBuC}_6\text{H}_4)$, showing the second-order effects of coupling to the niobium nucleus: the multiplet spacing decreases slightly from high to low frequency. The lines outside the main decet are spinning sidebands. The markers are at 1 kHz intervals

of the 1:2:3:2:1 quintet patterns. The spectra can be used to determine, at least qualitatively, the relative values of χ at different positions in a chain, which in turn depend on variations in local molecular mobility.

Of course, the appearance of splittings arising from either dipolar coupling, whether residual or full, or indirect coupling is contingent upon the lifetimes of the quadrupolar spin states being long compared with the frequency separations in the spin- $\frac{1}{2}$ spectra. If spin–lattice relaxation times of the quadrupolar nuclei become sufficiently short, the result is ‘self-decoupling’ (such as is frequently observed in solution state situations). In such cases a single line will be seen in the spin- $\frac{1}{2}$ spectrum. This is the situation¹⁰ for the ^{31}P spectrum of PCl_5 where sharp singlets are observed for the PCl_4^+ and PCl_6^- ions at room temperature but multiplets at low temperature. Of course, molecular motion (e.g. rotation of ions, as for PCl_5) may affect residual dipolar splittings both directly (by averaging D) and indirectly (by relaxing the S nucleus). ‘Self-decoupling’ can in principle also occur because of chemical exchange involving I – S bond breaking.

5 DEPARTURE FROM PERTURBATION THEORY

The first clear case of effects of dipolar coupling residual which did not involve the (^{13}C , ^{14}N) nuclear pair concerned the (^{31}P , ^{63}Cu) nuclei in bis(triphenylphosphine)copper(I) and related complexes, presented by Menger and Veeman.⁵ These authors published detailed theory, but the situation was beyond the validity of perturbation theory. Many examples involving the (^{31}P , ^{63}Cu) pair have since come to light, though some are susceptible to the perturbation approach.

The (^{13}C , $^{35/37}\text{Cl}$) case is interesting.^{11,12} Although there are simplifying features, since chlorine is univalent (and hence coaxiality of $\mathbf{J}$ and $\mathbf{D}$ can be assumed) and $J(\text{C}, \text{Cl})$ is negligibly small, the value of $|\chi|$ is sufficiently large (ca.

Figure 6 Carbon-13 CP MAS NMR spectra of sodium monochloroacetate: (a) 75.4 MHz; (b) 50.3 MHz, showing the second-order effects of coupling to chlorine.¹² The insets show expansions of the carboxyl region. The asterisks denote spinning sidebands

–70 MHz) that departures from perturbation theory can be observed. At modest magnetic fields (7.1 T and above), the 1:1 doublet predicted by perturbation theory is indeed observed [Figure 6(a)], but the splitting is smaller than predicted and is not inversely proportional to B_0 . However, it has been shown¹³ by simulation using exact theory that for the case $S = \frac{3}{2}$ the doublet splitting, s , can be adequately represented in the range $0.8 < R = |\chi/\nu_S| < 3.0$ by the cubic polynomial

$$s = D(0.581R + 0.033R^2 - 0.021R^3) \quad (8)$$

A cubic equation for s has also been derived for the $S = \frac{3}{2}$ case in which J_{iso} cannot be ignored.

For the (^{13}C , $^{35/37}\text{Cl}$) case, even equation (8) is inadequate at 4.7 T, since a broad 2:1:1 triplet is both predicted and observed^{11,12} [Figure 6(b)]. Figure 7 shows the theoretical line positions (centers of gravity) as a function of R for the case $I = \frac{1}{2}$, $S = \frac{3}{2}$ for positive χ and in the absence of $\mathbf{J}$. At high values of R , four lines are expected, and this links up with the expectation from inverse perturbation theory discussed below.

Molecular-level motion has a drastic effect on the ^{13}C spectra of sodium chloroacetates.¹² For the monochloro compound a clear doublet is seen for both the CH_2Cl and carbonyl carbons at 7.1 T and above, with the expected 2:1:1 triplet at 4.7 T. However sodium trichloroacetate shows a sharp line for each carbon at 7.1 T, not only at room temperature but also down to 163 K. The reason for this behavior undoubtedly lies in the facile internal rotation of the $\text{C}-\text{CCl}_3$ group.

Figure 7 Line positions (centers of gravity, units of D) for a spin-1/2 nucleus coupled to a spin-3/2 nucleus as a function of $R = \chi/\nu_S$ as obtained¹³ by the full theory for positive χ and assuming $J_{\text{iso}} = \Delta J = \eta = \beta^D = 0$

When J_{iso} needs to be taken into consideration and perturbation theory is inadequate, it has been shown¹³ that the sign of J_{iso} can be obtained from the spectrum (if the sign of χ is known). Thence $J(^{63}\text{Cu}, ^{31}\text{P})$ has been found¹³ to be negative.

6 QUADRUPOLEAR COUPLING DOMINANT

Olivieri has considered^{14,15} the case where the quadrupole coupling constant is very large. The dipolar and indirect couplings will still transfer the quadrupole information to the spin- $\frac{1}{2}$ nucleus under MAS conditions, giving rise to splittings in the spectra. For the case where $\mathbf{J}$ is axially symmetric and the three tensors $\mathbf{D}$, $\mathbf{q}$, and $\mathbf{J}$ are all co-axial, Olivieri showed¹⁴ that a quartet results when $S = \frac{3}{2}$. Each component is a powder pattern, with the centers of gravity forming two doublets with splittings, independent of the applied magnetic field, given by

$$s(\pm\frac{1}{2}) = |1.709J_{\text{iso}} + D'| \quad (9a)$$

$$s(\pm\frac{3}{2}) = \frac{3}{2}|2D' - J_{\text{iso}}| \quad (9b)$$

When the Zeeman S term begins to be significant with respect to the quadrupolar interaction, an inverse perturbation approach ('inverse' when compared to the considerations of Section 2 above) may be used.¹⁴ In this case equations (9a) and (9b) need to be modified, and the four centers of gravity are

$$\langle \Delta\nu(\pm\frac{1}{2}) \rangle = \mp(0.8546J_{\text{iso}} + 0.5D')$$

$$-2(J_{\text{iso}} + D')\frac{\nu_S}{\chi} \quad (10a)$$

$$\langle \Delta\nu(\pm\frac{3}{2}) \rangle = \pm\frac{3}{4}(2D' - J_{\text{iso}}) + 2(J_{\text{iso}} + D')\frac{\nu_S}{\chi} \quad (10b)$$

The spectrum is no longer symmetric, and the sense of the asymmetry depends on the relative signs of $J_{\text{iso}} + D'$, ν_S , and χ . Olivieri has also extended calculations¹⁵ of this type to

situations where $\mathbf{q}$ is not axially symmetric and for arbitrary relative orientations of $\mathbf{q}$ and $\mathbf{D}$.

Frequently, large χ implies the likelihood of rapid spin–lattice relaxation and therefore self-decoupling of S from the spin- $\frac{1}{2}$ nucleus in question. However, (^{13}C , $^{79/81}\text{Br}$) systems have been shown¹⁶ to approach the inverse perturbation case, and an example of a (^{31}P , ^{201}Hg) spin pair (with $D \ll J_{\text{iso}}$ in magnitude) even nearer the low-field limit has been reported.^{15,17}

1 INTRODUCTION

If a sample of liquid benzene is exposed to the Earth's magnetic field passing through it along a north–south direction, there will be a slight tendency for the molecules to turn their faces east–west (or up–down) and away from north–south. The original meaning of ‘orient’ was to face the east, so one might describe the benzene as slightly oriented, or aligned. The normal thermal motions of the molecules largely overcome this tendency, and one can calculate that at any instant the excess of east–west facing molecules over north–south facing molecules is approximately 1 in 10^{15} . In the study of NMR, this tendency to align in the magnetic induction $\mathbf{B}_0$ has been ignored until recently, since the effects on the NMR spectra have been too small to observe. However, the degree of alignment increases as the square of $\mathbf{B}_0$, and in today's spectrometers with $\mathbf{B}_0$ values of 10^5 or more times the Earth's field, the alignment is sufficient that perturbations of the NMR spectrum are often readily observed. This article gives an outline of the origin of the alignment, the nature of the changes produced in the spectrum, and some applications of these to the structure determination of molecules in solution, to molecular angular correlation, to ions, and to paramagnetic species.

2 ENERGETICS OF A RIGID MOLECULE IN ISOTROPIC SOLUTION IN A MAGNETIC FIELD

All objects, molecules, men, or galaxies, possess the property called magnetic susceptibility,¹ usually denoted by χ . When the object is placed in a magnetic field $\mathbf{H}_0$, a magnetic dipole $\mathbf{m}$ is induced in it, according to the equation

$$\mathbf{m} = \chi \mathbf{H}_0 \quad (1)$$

For diamagnetic molecules or ions, χ is negative and small, for paramagnetic species, it is usually positive and larger.

The act of putting a molecule in the magnetic field results in a change in energy of the system:

$$\Delta E = -\chi \mathbf{H}_0 \cdot \mathbf{B}_0/2 \quad (2)$$

$\mathbf{B}_0$ is related to $\mathbf{H}_0$ by the fundamental relationship

$$\mathbf{B}_0 = \mu \mathbf{H}_0 \quad (3)$$

where μ is the permeability. In all cases discussed here, μ differs insignificantly from μ_0 , the permeability of free space, so that one can rewrite equation (3) as

$$\Delta E = -\chi B_0^2/2\mu_0 \quad (4)$$

In the SI system, standardized in this Encyclopedia, the units of ΔE are joules, those of χ are m^3 per molecule, those of $\mathbf{B}_0$ are tesla, and those of μ_0 are $4\pi \times 10^{-7}$ tesla² m³ joule⁻¹. Much of the experimental work performed on magnetic alignment has been reported using cgs units, in which $\mu_0 = 1$ and χ is in cm³ per molecule. These literature values of χ can be converted into the SI system by multiplying by $4\pi \times 10^{-6}$. A few papers give χ in units of joule tesla⁻², collapsing μ_0 into χ .

For molecules which are not of tetrahedral or higher symmetry, χ is expected to be anisotropic, that is to differ when measured parallel to the x , y , and z axes of a molecule-fixed coordinate frame.² χ is then represented as a second-rank tensor, which, if the correct axes are chosen, will be diagonal:

$$\chi = \begin{bmatrix} \chi_{xx} & 0 & 0 \\ 0 & \chi_{yy} & 0 \\ 0 & 0 & \chi_{zz} \end{bmatrix} \quad (5)$$

Equation (4) must then be written in tensor notation:

$$\Delta E = -\mathbf{B}_0 \cdot \chi \cdot \mathbf{B}_0/2\mu_0 \quad (6)$$

In the absence of a magnetic induction, the molecules in solution undergo a random tumbling motion as a result of collisions with solvent molecules. However, in the presence of $\mathbf{B}_0$ there will be a torque tending to turn the molecule into its minimum energy position. Taking benzene as an example, we note that the susceptibility is most negative when measured along the six-fold axis, so the energy is highest when the six-fold axis is parallel to $\mathbf{B}_0$, and the alignment of benzene molecules with their planes parallel to $\mathbf{B}_0$ is preferred.

The degree of alignment of a particular axis i relative to $\mathbf{B}_0$ in the molecule is specified by the parameter S_{iB} , defined by³

$$S_{iB} = \langle \frac{3}{2} \cos^2 \theta_{iB} - \frac{1}{2} \rangle \quad (7)$$

where θ_{iB} is the angle between the axis i and $\mathbf{B}_0$, and the angle brackets indicate the expectation value of the enclosed expression. If $S_{iB} = 1$, the axis i is perfectly aligned parallel to $\mathbf{B}_0$, while if $S_{iB} = -\frac{1}{2}$ the axis i is always perpendicular to $\mathbf{B}_0$. $S_{iB} = 0$ implies completely random tumbling. S_{iB} may be evaluated assuming a Boltzmann distribution in the energies.⁴ Then

$$S_{iB} = \frac{\int_0^{2\pi} \int_0^\pi (\frac{3}{2} \cos^2 \theta_{iB} - \frac{1}{2}) e^{-\Delta E/kT} \sin \theta_{iB} d\theta_{iB} d\phi}{\int_0^{2\pi} \int_0^\pi e^{-\Delta E/kT} \sin \theta_{iB} d\theta_{iB} d\phi} \quad (8)$$

2 MAGNETIC FIELD INDUCED ALIGNMENT OF MOLECULES

Since ΔE is very small, the exponential can be approximated by $1 - \Delta E/kT$, and explicit integration of equation (8) gives

$$S_{iB} = \Delta\chi_{ii} B_0^2 / 15kT\mu_0 \quad (9)$$

with $\Delta\chi_{ii}$ equal to $\chi_{ii} - (\chi_{jj} + \chi_{kk})/2$. It is obvious that $S_{xB} + S_{yB} + S_{zB} = 0$. The degree of alignment increases as the square of the magnetic induction and is inversely proportional to the temperature. Taking benzene as an example, with a value of $\Delta\chi_{zz}$ of $-1.27 \times 10^{-33} \text{ m}^3$, and assuming $B_0 = 14.1 \text{ T}$ (600 MHz magnet), S_{zB} at 300 K is calculated to be -3.2×10^{-6} .

3 EFFECTS OF ALIGNMENT ON HIGH-RESOLUTION NMR SPECTRA

Two types of nuclear interaction have been observed to give rise to new or additional splittings in high-resolution spectra of samples in which the molecules are partially aligned by the magnetic induction: magnetic dipole interaction,⁵ and electric quadrupole interaction.⁶ Completely random tumbling averages these interactions to zero, so no splitting is observed. The rapidly fluctuating torques resulting from these interactions are evidenced, however, by the relaxation. However, if the tumbling is nonrandom, such that a small alignment occurs, these interactions are not completely averaged to zero, and effects on line positions and splittings are observed.

3.1 Magnetic Dipolar Interaction

An (oversimplified) model may be used. Two magnetic nuclei A and B are attached to the framework of a molecule, which is undergoing rapid tumbling. The magnetic moment of nucleus A is taken as parallel to the magnetic induction. The component of the magnetic field parallel to $\mathbf{B}_0$ generated by nucleus A at nucleus B is then given by¹

$$H_B = m_A(3 \cos^2 \theta_{nB} - 1)/r_{AB}^3 \quad (10)$$

where θ_{nB} is the angle between the internuclear axis and $\mathbf{B}_0$. If all orientations of the internuclear axis are equiprobable, equation (10) integrates to give $\langle H_B \rangle = 0$. On the other hand, if the internuclear axis has a degree of alignment S_{nB} , then

$$\langle H_B \rangle = 2m_A S_{nB} / r_{AB}^3 \quad (11)$$

This field would add to $\mathbf{H}_0$ causing a shift in the frequency of the NMR signal from nucleus B. If the moment of A were antiparallel to $\mathbf{B}_0$, the opposite shift would be observed. Thus a doublet would be produced. In the quantum mechanical formulation, the strength of the interaction is represented by D_{AB} , which is given by

$$D_{AB} = -\gamma_A \gamma_B \hbar S_{nB} / 2\pi^2 r_{AB}^3 \quad (12)$$

The observable splittings are directly related to D_{AB} . It is now necessary only to relate S_{nB} to χ :⁴

$$S_{nB} = \frac{2}{3} \sum_{i=x,y,z} \Delta\chi_{ii} \left(\frac{3}{2} \cos^2 \theta_{in} - \frac{1}{2} \right) B_0^2 / 15kT\mu_0 \quad (13)$$

where θ_{in} is the angle between the i th axis of the susceptibility tensor and the internuclear axis. Combining equations (12) and (13), and noting that the spectrometer frequency ν_A is equal to $\gamma_A B_0 / 2\pi$, the practical formula is obtained:

$$D_{AB} = -5.10 \times 10^{15} \nu_A \nu_B \times \sum_{i=x,y,z} \chi_{ii} \left(\frac{3}{2} \cos^2 \theta_{in} - \frac{1}{2} \right) / T a_{AB}^3 \quad (14)$$

where a_{AB} is the internuclear distance (in nanometers).

The effect of D_{AB} on the spectrum has been thoroughly explored in studies of molecules partially aligned by solution in liquid crystal solvents.⁷ For two spins with identical Larmor frequencies, the spectrum is a doublet with splitting $3D_{AB}/2$. An example of such a splitting is shown in Figure 1. The signal arises from two methylene protons attached to a porphyrin ring in the zinc vinylphylloerythrin-pyridine complex (**1**), with the internuclear axis parallel to the four-fold symmetry axis of the ring. The observed doublet splitting of 1.98 Hz observed at 600 MHz, implies $D_{HH} = 1.32 \text{ Hz}$. Taking a as 0.178 nm, T as 296 K, $\theta_{zn} = 0$, and $\chi_{xx} = \chi_{yy}$, gives $\Delta\chi_{zz} = -11.9 \times 10^{-33} \text{ m}^3$. The $\Delta\chi_{zz}$ of the complex is the sum of $\Delta\chi_{zz}$ for the porphyrin ($-12.5 \times 10^{-33} \text{ m}^3$) and $-(\frac{1}{2})\Delta\chi_{zz}$ for the pyridine ligand ($-1.19 \times 10^{-33} \text{ m}^3$), in agreement with values obtained by other methods.⁸

If the Larmor frequencies of the two nuclei differ by much more than D_{AB} and J_{AB} , the observed doublet spacing is simply $J_{AB} + D_{AB}$. The addition is algebraic,⁷ so if the sign and magnitude of J_{AB} are known from other studies, the sign and magnitude of D_{AB} can be determined. As an example of this, a second porphyrin containing a similarly situated methylene group was studied in methyl pyropheophorbide A (**2**). The pyrrole ring adjacent to the methylene was reduced, rendering the methylene protons inequivalent. They now gave rise to AX type doublets, with a splitting $J_{HH} + D_{HH}$ of 20.17 Hz at 5.87 T, 19.95 Hz at 7.05 T, 19.51 Hz at 11.75 T, and 19.25 Hz at 14.09 T. The plot of these splittings versus B_0^2 is a straight line with intercept $J_{HH} = -20.25 \text{ Hz}$, and $D_{HH} = +1.00 \text{ Hz}$ at 14.09 T. Application of equation (14) yields $\Delta\chi = -10.1 \times 10^{-33} \text{ m}^3$. The reduction of the pyrrole ring has partially interrupted the circuit of π electrons responsible for the ring current and for the large anisotropic susceptibility of porphyrins.

Figure 1 The doublet arising from the direct magnetic dipole interaction in zinc vinylphylloerythrin-pyridine complex

Finally, if the Larmor frequency difference between A and B and $J_{AB} \pm D_{AB}$ is of comparable magnitude, second-order effects are expected. The exact calculation of J_{AB} and D_{AB} from such spectra has been worked out in detail, in connection with the spectroscopy of solutes in liquid crystal solvents.⁷ It has been shown⁹ that the observation of the second order effects in suitable cases provides a sensitive method for detecting and measuring very small values of D_{AB} .

3.2 Electric Quadrupole Interaction

For most quadrupolar nuclei, the relaxation induced by the interaction of the nuclear quadrupole moment with the electric field gradient at the nucleus broadens the signals sufficiently to obscure the effects produced by molecular alignment. However, the quadrupole coupling constant for deuterium in a large variety of molecules is small, lying in the range 100–300 kHz, and the broadening is small enough that splittings arising from the quadrupole interaction can be seen in the ^2H NMR spectrum.

For a single deuterium atom, if molecular tumbling is not random, the signal consists of a doublet: the transitions correspond to the changes $m(-1 \rightarrow 0)$ and $m(0 \rightarrow 1)$. The frequency separation of the doublet $\Delta\nu_Q$ is given by

$$\Delta\nu_Q = 3eQ\langle V_{B_0} \rangle / 2h \quad (15)$$

where eQ is the nuclear electric quadrupole moment, and $\langle V_{B_0} \rangle$ is the expectation value of the electric field gradient along the direction of B_0 . It is convenient to establish a second molecule-fixed coordinate frame, x', y', z' , in which the electric field gradient tensor is diagonal, and to define $\nu_{x'}$, $\nu_{y'}$, and $\nu_{z'}$ as the quadrupole splittings which would be observed if the molecule were fixed with the x' , y' , and z' axes parallel to B_0 , respectively. Then,⁷

$$\Delta\nu_Q = \frac{2}{3} \sum_{i=x',y',z'} \nu_i \sum_{j=x,y,z} \cos^2 \theta_{ij} S_{jj} \quad (16)$$

The electric field gradient tensor is traceless, implying $\nu_{x'} + \nu_{y'} + \nu_{z'} = 0$. Quadrupole coupling constants for carbon-bound deuterium have been measured by NMR relaxation methods, Zeeman microwave spectroscopy, NMR studies of deuterated molecules in liquid crystal solvents, and nuclear quadrupole resonance spectroscopy of solids.¹⁰ The maximum splittings, $\nu_{z'}$ range from 225 to 300 kHz, with ^2H in similar chemical environments clustered together: ^2H attached to a benzene ring has $\nu_{z'}$ equal to 275 ± 5 kHz. Returning once again to benzene as an example, with $\nu_{z'} = 279$ kHz, $\nu_{x'} \approx \nu_{y'} = -139.5$ kHz, $\Delta\chi = -1.27 \times 10^{-33} \text{ m}^3$, $B_0 = 14.09 \text{ T}$, $T = 300 \text{ K}$, and $\theta_{zz'} = 90^\circ$, ν_Q is calculated using equation (16) to be 0.45 Hz. Figure 2 shows a ^2H NMR spectrum of monodeuterobenzene; the spectrum is resolution enhanced, with proton decoupling. The observed splitting (0.46 Hz) agrees well with the expected value.

Second-order effects are observed in the spectra when chemical shifts are zero or of comparable magnitude to J_{AB} and ν_{QA} or ν_{QB} . This complication prevents the direct observation of ν_Q in hexadeuterobenzene, which gives rise to a spectrum with numerous overlapping transitions.¹¹

3.3 Anisotropic Chemical Shift

If the sample molecules possess anisotropic magnetic susceptibilities and also contain nuclei with anisotropic

Figure 2 Deuteron quadrupole splitting of the deuteron signal from benzene- d_1 , with proton decoupling

chemical shieldings, it is expected that the shift will not be linearly related to B_0 . The reason for this is clear: if the molecule is tumbling randomly, the average chemical shift $(\sigma_{xx} + \sigma_{yy} + \sigma_{zz})B_0/3$ will be observed; if the molecules are partly aligned, with alignment parameters S_{xB} , S_{yB} , and S_{zB} , the observed shift will be

$$2 \sum_{i=x, y, z} S_{iB} \sigma_{ii} B_0/3$$

Despite concerted effort, no such nonlinear shifts have been demonstrated to date. The difficulty is that the expected effects are very small, and easily masked by shifts arising from extraneous factors such as temperature.

4 APPLICATIONS

From the above, it can be seen that the dipolar splitting observed between two nuclei in a molecule in a high B_0 relates the length and direction of the internuclear vector to χ . Similarly, the observed quadrupole splitting relates the electric field gradient tensor $\mathbf{V}$ and χ . If χ is known, or can be estimated accurately, then information is obtained on the internuclear vector or on $\mathbf{V}$, i.e. structural information. On the other hand, if the structure is known (the length and direction of the internuclear vector relative to the principal axes, or direction and the strength of the electric field gradient), χ may be determined. For organically bound ^2H , the largest component of $\mathbf{V}$ (V_{zz}) is directed along the C– ^2H (or N– ^2H , O– ^2H , etc.) bond, and the asymmetry, $V_{xx} - V_{yy}$ is negligible. Even for ^2H attached to trigonal carbon, the asymmetry is normally less than 5% of V_{zz} .

4.1 χ , Systematics and Determination

In addition to the high-field NMR method, there are several methods for determining χ . In the crystal flip angle method,² a single crystal of the sample is suspended by a quartz fiber in a transverse magnetic induction and the torque required to cause the crystal to turn from its lowest energy state through its highest energy state is measured. In the Cotton–Mouton method,¹² the partial alignment of molecules in the liquid or gaseous state by B_0 is measured by observing the optical birefringence. In the Zeeman microwave method,¹³ the Zeeman effect on rotational spectra is observed. Extensive measurements have been made using all these methods, often on the same molecule; the results are generally in good agreement.¹⁴ For example, for benzene, single crystal measurements yielded a value for $\Delta\chi$ of $-1.24 \times 10^{-33} \text{ m}^3$, three independent measurements by the Cotton–Mouton method gave -1.31 , -1.32 , and $-1.33 \times 10^{-33} \text{ m}^3$, and measurements by high-field NMR gave $-1.27 \times 10^{-33} \text{ m}^3$. With no electric dipole moment, benzene could not be studied directly by rotational spectroscopy.

All these measurements have demonstrated that Pascal's additivity scheme¹⁵ for the isotropic diamagnetic susceptibility can be extended to χ , the molecular susceptibility tensor, i.e. that χ can be expressed as the sum of bond susceptibility tensors χ_b , or of atom susceptibility tensors χ_a , with the addition of χ_e (a susceptibility tensor ascribable to the

delocalized circulation of electrons).¹³ There is a considerable amount of literature covering χ_e in aromatic and antiaromatic compounds; an alternative name for this delocalized circulation is 'ring current'. In early studies the existence of the ring current and its magnitude were inferred from measurements of 'exaltation',¹⁵ the amount by which χ exceeds $\Sigma\chi_b$ or $\Sigma\chi_a$. The circulation is in the plane of the aromatic or antiaromatic systems, so χ_e has zero elements for χ_{xx} and χ_{yy} ; χ_{zz} is negative if the molecule is aromatic, and positive if it is antiaromatic.¹⁶

Acyclic compounds do not exhibit exaltations, and fit the additive scheme well, although multiple heavy atom substitution on carbon causes deviations. Single and triple bond susceptibility tensors are axial, that is $\chi_{xx} = \chi_{yy}$. If only single and triple bonds are present, S_{nB} for any axis can be determined using

$$S_{NB} = \sum_{\text{bonds}} \left(\frac{3}{2} \cos^2 \theta_{nB} - \frac{1}{2} \right) \Delta\chi_b B_0^2 / 15kT\mu_0 \quad (17)$$

Double bond susceptibility tensors have three different components, so the full version of equation (9) is required. Cyclic compounds, even saturated small ring compounds, such as cyclopropane, cyclobutane, and cyclopentane, show significant contributions from χ_e . The exact nature of the delocalization is uncertain, but three- and five-membered rings have negative χ_e , while four-membered rings have positive χ_e .

The susceptibility tensor for most rigid molecules is a hard property, i.e. it is not affected appreciably by the environment. χ is the same, within experimental error, whether measured in the gas, liquid, or solid phase. If the molecular electronic or geometrical structure is actually changed by the environment, χ will change. For example, different solvents which produce a different weighting of the polar and nonpolar resonance forms in *N*-methyl-2-pyridone cause different quadrupole splittings to be observed for the deuterated compound.

Extensive analyses of bond susceptibility additivity schemes have been presented in articles by Flygare¹³ and Haberditzl.¹⁷

4.2 Determination of Structure: Rigid Molecules

As an example of structural elucidation, we consider the study of the dihydrogen complex of the bridged bis(ruthenium porphyrin) · H_2 complex (3).¹⁸ The structure of the $\text{B}(\text{RuP})_2$ framework is well established. The structural question to be answered is: What is the arrangement of the H_2 ? How far apart are the hydrogen atoms, and what angle does the H–H axis make with the molecular z axis (Ru–Ru axis)?

The susceptibility tensor for the complex can be estimated within a few per cent by adding the known tensors for the two porphyrins, the phenylimidazolyl groups, and the biphenylene bridging group, using the summation

$$\Delta\chi_{zz} = \sum_{\text{groups}} \left(\frac{3}{2} \cos^2 \theta_{zz'} - \frac{1}{2} \right) \Delta\chi_g \quad (18)$$

with $\theta_{zz'}$ being the angle between the molecular z axis and the normals to the ring planes of the individual groups. The anisotropy of the C–C bonds joining the biphenylene and porphyrin groups and of H_2 are less than $0.1 \times 10^{-33} \text{ m}^3$ and do not contribute significantly to the sum, which gives

$\Delta\chi_{zz} = -24.0 \times 10^{-33} \text{ m}^3$. Measurements of the H–H magnetic dipolar splitting were made at 620 MHz (14.56 T). S_{zB} is calculated to be -6.61×10^{-5} at this B_0 .

The H_2 signal at 620 MHz is a doublet with a splitting of $\pm 7.37 \pm 0.05 \text{ Hz}$. D_{HH} is thus $\pm 4.91 \pm 0.03 \text{ Hz}$. Using equation (14), one finds:

$$\langle \frac{3}{2} \cos^2 \theta_{zn} - \frac{1}{2} \rangle / r_{\text{HH}}^3 = \pm 0.309 \times 10^{24} \quad (19)$$

The sign of D_{HH} was not known, but was determined by observing the field dependence of the splitting $J_{\text{HD}} + D_{\text{HD}}$ for the complex with HD. The sign of J_{HD} is known to be positive, so the decreasing magnitude of the splitting with increasing B_0 means that D_{HD} and thus D_{HH} are negative. The internuclear distance was deduced by relaxation time measurements to be $0.121 \pm 0.009 \text{ nm}$. This yields $\langle (3/2) \cos^2 \theta_{zn} - (1/2) \rangle = -0.54 \pm 0.05$. Since $\langle (3/2) \cos^2 \theta_{zn} - (1/2) \rangle$ cannot be more negative than $-\frac{1}{2}$, it appears that θ_{zn} must be very close to 90° ; the H–H axis is perpendicular to the molecular z axis.

4.3 Study of Molecules with Internal Motion

As an example, a study of styrene and 1- and 2-vinylnaphthalene is outlined.¹⁹ The motion of interest is the rotation of the vinyl group about the single bond joining it to the aromatic ring. The parameter measurable by high field studies is the expectation value, $\langle \sin^2 \alpha \rangle$, where α is the dihedral angle between the planes of the vinyl group and the ring. In the study, the quadrupole splittings of the deuterium signals were measured for styrene with deuterium substituted in all positions of the vinyl and phenyl groups.

Addition of the known group susceptibility tensors for vinyl and phenyl groups suggests that the principal axis z of styrene is very nearly perpendicular to the phenyl ring, regardless of α , and that $\chi_{xx} \approx \chi_{yy}$. The equality of the observed splittings for the *ortho*, *meta*, and *para* deuterons in the phenyl group is consistent with this, and their magnitude at 14.57 T indicates a value of $\Delta\chi_{zz} = -1.45 \times 10^{-33} \text{ m}^3$. The determination of $\langle \sin^2 \alpha \rangle$ is then an exercise in solid trigonometry: one has to calculate $\langle \cos^2 \theta_{zz'} \rangle$ relating the molecular z axis to the z' axis

of the electric field gradient tensor (the C–D bond axis) for the α and *trans*- β deuterons in the vinyl group. These are related by

$$\langle \cos^2 \theta_{zz'} \rangle = \langle \sin^2 \alpha \rangle \langle \sin^2 \beta \rangle \quad (20)$$

where β is the angle between the C–D bond and the C–C bond joining the vinyl and phenyl groups. For the deuteron in the *cis*- β position, $\beta \approx 0^\circ$, the C–D axis is parallel to that of the *para*-deuteron, regardless of internal rotation of the vinyl group. The ratio of the splittings is thus a measure of the ratio of the quadrupole couplings for the phenyl–D and vinyl–D nuclei (185 and 181 kHz, respectively), which is in agreement with previous measurements. For the α and *trans*- β deuterons, β is taken as 71° . From the observed splittings, it is then found that $\langle \sin^2 \alpha \rangle$ is 0.081 and $\sin^{-1} \langle \sin^2 \alpha \rangle^{1/2}$ is 16.5° . If the splitting were negative rather than positive, one would obtain $\langle \sin^2 \alpha \rangle = 0.666$ and $\sin^{-1} \langle \sin^2 \alpha \rangle^{1/2} = 55^\circ$, but this can be eliminated, because the value of $\Delta\chi_{zz}$ obtained would be $-1.31 \times 10^{-33} \text{ m}^3$, which is a much smaller value than that indicated by the phenyl–D splittings. Similar measurements on 2-vinylnaphthalene indicated $\langle \sin^2 \alpha \rangle$ gave values the same as those for styrene, within experimental error, while for 1-vinylnaphthalene, $\sin^{-1} \langle \sin^2 \alpha \rangle^{1/2} \approx 40^\circ$, suggesting steric interference between the vinyl group and the *peri*-hydrogen atom in the planar arrangement.

4.4 Angular Correlation in the Liquid State

Even in the absence of a magnetic flux, a molecule (A) which is not isotropic interacts with neighboring anisotropic molecules (B) in such a way that they do not tumble randomly, but adopt preferred orientations with respect to A. A strong limiting case of this is association; if molecule A binds to molecule B, for example with a hydrogen bond or by ionic attraction, then A and B do not move independently, but tumble together synchronously. More subtle interactions can also induce molecular correlation: the electric polarizability, electric dipole moment, quadrupole moment, or higher moments, may interact with any of these of the B molecules; the shapes of molecules A and B may be conducive to better packing in particular mutual orientations. Molecule A may influence several molecules of molecule B, and vice versa. Finally, A and B may be different species (solute and solvent), or the same (neat liquids). Angular correlations may also be characterized by ordering parameters $S_{ij'} = \langle (3/2) \cos^2 \theta_{ij'} - (1/2) \rangle$, where $\theta_{ij'}$ is the angle between the i th axis of A and the j th axis of B. If molecules A and B are identical, one may define Kirkwood's²⁰ parameter $g_{ii'}$ as

$$g_{ii'} = 1 + \sum_n S_{ii'} \quad (21)$$

The summation is taken over all neighboring B molecules, and the unity term represents the angular correlation of A with itself. For example, if $g_{zz'}$ were found to be 2.00 for neat benzene, a conceivable (though incorrect) explanation would be that neat benzene consists entirely of face-to-face dimers, with parallel z axes. For neat samples,

$$S_{iB}^A = g_{ii'} \Delta\chi_{ii} B_0^2 / 15kT\mu_0 \quad (22)$$

while for solute A in solvent B

$$S_{iB}^A = \left(\Delta\chi_{ii}^A + \frac{2}{3} \sum_n \sum_{j'=x',y',z'} (S_{ij'} \Delta\chi_{jj'}) \right) B_0^2 / 15kT\mu_0 \quad (23)$$

In order to measure the degree of molecular alignment caused by the induction, free of solvent angular correlation effects, it is customary to employ dilute solutions in solvents which are themselves exactly or nearly magnetically isotropic. Ideal solvents would include CCl₄, SiMe₄, CMe₄, and SF₆. Good, though not perfect, solvents include water, liquid ammonia, diethyl ether, and cyclohexane. The angular correlation in a number of neat liquids has been studied by comparing the alignments observed in dilute solution in isotropic solvents, and in the neat liquid. The value of $g_{zz'}$ found for benzene was 0.86, which implies a negative value for $S_{zz'}$. The rings of neighboring benzene molecules tend to form angles greater than 54.7°, rather than stack, pancake fashion.¹⁰

4.5 Paramagnetic and/or Charged Species

Paramagnetic or charged species are partially aligned in a magnetic field in the same way as neutral diamagnetic molecules. Since paramagnetic susceptibilities are usually much larger than diamagnetic susceptibilities, it is not surprising that the anisotropies of the paramagnetic susceptibilities are also much larger, and the degree of alignment correspondingly greater. Thus the first observation⁵ of a dipolar splitting in isotropic solution was made on the paramagnetic cobalt complex bis[*p*-tolyl-tris(pyrazolyl)borato]cobalt(II) (4). Lanthanide shift reagents exert their effects by virtue of their large anisotropic susceptibilities; consequently, molecules complexed with shift reagents exhibit large dipolar and quadrupolar splittings of the type described here, even at moderate field strengths. A very interesting study of the susceptibility tensor for a ferric porphyrin has been reported.²¹

Studies of organic cations and anions have also been made.²² Ion pairing probably occurs in the cases studied, although the counterions are expected to be nearly isotropic and thus correlation effects would be negligible. Of course the electronic structure of the organic ion itself may be strongly affected by the counterion. Values of χ_e have been deduced and related to the electronic structure of the ions.

1 INTRODUCTION

Think for a moment about the area of the North American continent known as the 'Great Plains'. In the twenty thousand years before the coming of the Europeans to this area, the thirty millions of original peoples were able to see herds of antelope, and of native bison, so multitudinous that it took hours for a running herd to pass. There grew the native prairie grasses that sustained them, such as the Big Bluestem, Little Bluestem, and Indian Coneflower used by the indigenous peoples for medicinal purposes, and only recently found to be of medicinal use to the descendants of the descendants of the first Europeans. One of the stunning sights that these newcomers recorded in their arrival to the center of this 'New World' was the effect of the wind on the seas of prairie grasses, since replaced by corn and soybeans, which moved like 'waves of the sea'—seemingly endlessly abundant then, but since almost become extinct. Where had lived the peoples whose names themselves had the music of the prairies associated with them—the 'Illinois', 'Sioux', 'Ojibway', 'Menominee', 'Pawnee', 'Mesquakie' ... —were Katherine Lee Bates's (author of the song 'America the Beautiful') 'amber waves of grain', each stem coherently moving in concert with millions of others to produce the effect of being on an immense ocean, through which sailed the 'prairie schooner covered wagons' of those seeking more living room.

Now consider that sight, so vast and continuous that it drove some of the early invaders to madness with time. Here were countless billions of single, almost identical stems, enough to be called by Gibbs an 'ensemble' of those elegantly beautiful flora. The effect of waves of an ocean was produced by these two-meter high plants waving in phase with each other under the excitation of a wind, with wavelength long compared with the separation between the individual stems, and powerful enough to cause millions of them to move in concert so they appear to be a single body. In this example, we are given some hint of what the word 'coherence' can mean: the movement, in phase, in both time and space, of an ensemble of identical

systems, such that vast portions of them can be detected being in a state which describes a macroscopic entity.

In magnetic resonance, we produce a coherence in phase among individual spins in an ensemble by excitation with a radiofrequency having a wavelength enormous compared with the separation between individual nuclear spins. We generally detect such coherence of an ensemble of spins waving in the static field of our magnet via the voltage induced by a sufficiently large number in an inductor such that a signal is detectable above the Johnson noise (but see *Optically Enhanced Magnetic Resonance*). Since the inductor is a dipole producer, and a dipole detector, i.e., a detector of coherence associated with transitions between states differing in spin quantum number by a single quantum, we can only directly detect *single* quantum coherence ($\Delta k = 1$) of such an ensemble.

In the present discussion, we want to elucidate the meaning of multiple quantum coherence in the special case of dipolar coupled spin- $\frac{1}{2}$ systems, and to illustrate how the experiment is accomplished to produce and detect such a phenomenon. To do so, it is necessary to first amplify the meaning of 'coherence'. Then we shall proceed to discuss the production of multiple quantum coherence, and finally the means used for detection. To begin, we use the familiar example of the ideas behind the development and detection of single quantum coherence in spin- $\frac{1}{2}$ systems. Then the concepts used to produce *multiple* quantum coherence ($\Delta k \geq 2$) in ensembles of dipolar coupled spin- $\frac{1}{2}$ systems are developed. Thought experiments are used to illustrate conversion of populations ($\Delta k = 0$) into multiple quantum coherence with the use of coherent averaging to produce a multiple quantum propagator (quite a lovely introduction to the subject of propagators in quantum mechanics is given by Mattuck¹). Propagators that develop multiple quantum coherence in steps of single and double quanta are discussed and illustrated. Experimental details concerning the manipulations necessary to perform the experiments are given. Experimental results using a single quantum propagator are shown for adamantane, and for a liquid crystal containing isolated clusters of 21 protons. The aim of this work is to present, in an easily understandable manner, and perhaps with a fresh perspective, the ideas behind the creation and detection of multiple quantum coherence in ensembles of homonuclear dipolar coupled spin- $\frac{1}{2}$ systems. To this end, both theoretical ideas and experimental details will be presented so that readers will have the background to perform such experiments on their own instruments, given the appropriate phase shifting capabilities.

Before beginning to discuss the specifics of coherence, and its production and detection, we note that spin counting by multiple quantum coherence is one of a variety of possible two-dimensional NMR experiments²⁻⁴ that first began to appear in the mid 1970s and have since been extensively reviewed.⁵⁻⁹ In the specific case of using multiple quantum coherence (MQC) to enumerate numbers of strongly coupled spins in ensembles of coupled clusters of protons in solids,^{10,11} the initial work developed multiple quantum coherence in steps of two quanta, such that values of MQC, k , of 0, 2, 4, 6, ... , or (depending on the state of the system prepared before the use of multiple pulse techniques to produce MQC) 1, 3, 5, ... , might be detected. Later work (see below) resulted in the use of pulse sequences that developed MQC in steps of one quantum, such that values of $k = 0, 1, 2, \dots$ could be detected.

In liquids, the coupling mechanism used to produce multiple quantum coherence is the two-body scalar or J coupling. The secular portion of the spin space part of this interaction is $\hat{I}_z \hat{S}_z$ for the heteronuclear case. In solids, the case to be discussed here, the interaction is the two-body homonuclear dipolar coupling between spin- $\frac{1}{2}$ systems, e.g., among protons in a solid. The secular portion of the ‘spin space’ part of this interaction is $\hat{I}_1 \cdot \hat{I}_2 - 3\hat{I}_{z1}\hat{I}_{z2}$. The pulse sequences used to develop MQC in the latter case will therefore differ from those used for the former, in the same sense that the dipolar echo sequence $(\tau, 90_x^\circ, \tau, 90_y^\circ, \tau)$ (see **CRAMPS**) differs from the spin echo sequence $(\tau, 180_x^\circ, \tau)$ (see **Echoes in Solids**). However, the extension of the present description to heteronuclear dipolar coupling and to scalar coupling should be obvious, with the techniques used to generate and detect MQC being more easily achieved than in the present case.

2 SINGLE QUANTUM COHERENCE

We first ask: ‘What do we observe in an NMR experiment?’ The answer is always a transverse component of spin angular momentum. With phase detection along y in the rotating frame, what is observed is

$$\text{FID} \sim \langle \hat{I}_y(t) \rangle = \text{Tr} \{ \hat{\rho}(t) \hat{I}_y \} \quad (1)$$

From this formalism, it is immediately obvious that we are invoking the use of the quantum statistical method, in that the density operator $\hat{\rho}$ must be used to describe the phenomena discussed here.¹² Statistical thermodynamics enters when we consider that the ensemble in question is prepared in some equilibrium state before observation, i.e., we expose an ensemble of nuclear spins I in a field until equilibrium is achieved under the Zeeman interaction $\hat{\mathcal{H}}$, and

$$\hat{\rho}(0) \equiv \hat{\rho}^{\text{equilibrium}} = \frac{1}{Z} \exp \left(-\frac{\hat{\mathcal{H}}}{k_B T} \right) \sim \sum_k \hat{I}_{zk} \quad (2)$$

$k = 1, 2, \dots$

is the operator form of $\hat{\rho}$. Z is the ensemble partition function and k_B Boltzmann’s constant.

The FID, whose time dependence is given by $\hat{\rho}(t)$, and whose phase is specified in this case by the operator $\hat{I}_y$, is driven by the presence of time-independent Hamiltonians $\hat{\mathcal{H}}$ as follows:

$$\hat{\rho}(t) = \exp(-i\hat{\mathcal{H}}t) \hat{\rho}(0) \exp(i\hat{\mathcal{H}}t) \quad (3)$$

The spectrum is obtained by Fourier transformation of the FID. We remind ourselves of the quantum mechanics involved in this statement with a short review.

We consider an ensemble of weakly interacting identical systems, each described by a set of single particle stationary states $|m_a\rangle$, which are eigenstates of the z component of nuclear spin angular momentum such that $\hat{I}_z|m_a\rangle = a|m_a\rangle$. These identical systems for purposes of the present discussion might be ‘isolated’ nuclear spins (e.g., ^{13}C nuclei at a natural abundance of 1.1% decoupled from other nuclei via strong rf decoupling), or isolated pairs of nuclear spins (e.g., pairs of

protons in partially hydrated calcium sulfate, $\text{CaSO}_4 \cdot x\text{H}_2\text{O}$, with $x < 2$), or many (of order 10^{23}) protons in strongly dipolar coupled solids. If a system consists of more than a single spin- $\frac{1}{2}$ nucleus then the stationary states describing the system can be arranged into linear combinations of products of single particle states, which we denote by $|M_a\rangle$, which are eigenfunctions of the square of the total spin angular momentum operator, $\hat{I}^2$, and of the z component of the angular momentum, $\hat{I}_z$.

Two of these many body states, $|M_a\rangle$, $|M_b\rangle$, differ by $k = a - b$ in the z component of the angular momentum. Further, the state of each system can in general be a time-dependent superposition of these stationary states:

$$|\Psi(t)\rangle = \sum_j c_j(t) |M_j\rangle \quad (4)$$

where the phase factor of the j th stationary state, $e^{i\phi_j}$ has been implicitly included in the time-dependent amplitude $c_j(t)$.

For example, in ensembles that consist of coupled pairs of spin- $\frac{1}{2}$ nuclei, each with stationary states α and β , where the coupling interaction is small compared with the Zeeman interaction, the normalized stationary states of the coupled systems, which can be arranged to be eigenfunctions of the square of the total spin operator, $\hat{I}^2$, and of the z component of spin, $\hat{I}_z$, are $|\alpha(1)\rangle|\alpha(2)\rangle$, $\frac{1}{\sqrt{2}}[|\alpha(1)\rangle|\beta(2)\rangle \pm |\beta(1)\rangle|\alpha(2)\rangle]$ and $|\beta(1)\rangle|\beta(2)\rangle$, which are the four two-particle functions describing the triplet and singlet spin states. Two coupled spins can have maximum total spin quantum number $I = 1$, and z component $-I < \langle \hat{I}_z \rangle < I$ in steps of unity. Three coupled spins can have maximum total spin quantum number $I = \frac{3}{2}$, etc.

We remember that the statistical probability of finding any system in stationary state $|M_s\rangle$ is

$$P_s = \overline{c_s^*(t)c_s(t)} = \overline{c_s(t)c_s^*(t)} \quad (5)$$

where the overbars mean an ensemble average. The operator $\hat{\rho}$ is defined by the ensemble average of the product $\hat{\rho} = |\psi\rangle\langle\psi|$ such that the i,j th matrix element is

$$\rho_{kj} = \overline{\langle k|\Psi\rangle\langle\Psi|j\rangle} = \overline{c_k c_j^*} \quad (6)$$

A nonvanishing value of ρ_{ss} therefore represents a population of the state $|M_s\rangle$. An observable signal in NMR means a nonvanishing value of $\rho_{s,s+1}$. This means that in the ensemble of systems being observed, there is a *phase coherence* associated with system states $|M_s\rangle$ and $|M_{s+1}\rangle$. We designate this a single quantum coherence. This is to say that we observe a decaying oscillation resulting from an ensemble in which the time-dependent state responsible for the behavior of each system is a superposition of two states differing from each other by a single quantum, *and having the same phase*. What does this mean? With the basis set for a spin- $\frac{1}{2}$ system being $|\alpha\rangle$ and $|\beta\rangle$, and for the k th basis state $|k\rangle$, the amplitude factor being $C_k = |C_k|e^{i\phi_k}$, an individual spin- $\frac{1}{2}$ system will have single particle wavefunction $|\psi\rangle = |C_\alpha|e^{i\gamma}|\alpha\rangle + |C_\beta|e^{i\phi}|\beta\rangle$. Here γ and ϕ are the phases of the single particle basis set functions, and the C_k will in general be time-dependent. A

very special k th single particle wavefunction in which the phase δ_k on the two basis functions is the same,

$$|\psi_k\rangle = e^{i\delta_k} \sqrt{\frac{1}{2}}(|\alpha_k\rangle + i|\beta_k\rangle) \quad (7)$$

is a *phase coherent superposition* of the two states that differ by $k = 1$ in the z component of the angular momentum. This system can be prepared by starting at time equal to zero with a single particle wavefunction $e^{i\delta_k}|\alpha\rangle$, and turning on an rf pulse, *operating on a timescale short compared with any dephasing tendency of the ensemble*, which rotates the z magnetization associated with the state $|\alpha\rangle$ by 90° , and converts it into the transverse magnetization described by the above superposition. *For this special combination*, $\langle\psi_k|\hat{I}_{yk}|\psi_k\rangle = \frac{1}{2}$. In an ensemble of spin- $\frac{1}{2}$ noninteracting systems represented by such a phase coherent superposition, $|\psi_{\text{tot}}\rangle = \Pi_k|\psi_k\rangle$, and for such an ensemble we find the ensemble average to be

$$\begin{aligned} \langle\hat{I}_y\rangle &= \langle\psi|\hat{I}_y|\psi\rangle \\ &= \frac{1}{N} \prod_k e^{-i\delta_k} \sqrt{\frac{1}{2}}(\langle\alpha_k| - i\langle\beta_k|) \left(\sum_{k'} \hat{I}_{yk'} \right) e^{i\delta_k} \\ &\quad \times \sqrt{\frac{1}{2}}(|\alpha_k\rangle + i|\beta_k\rangle) \\ &= \frac{1}{2} \end{aligned} \quad (8)$$

because the phase factors cancel! Another way of saying this is that

$$\rho_{\alpha\beta} = \frac{1}{N} \sum_k |C_{\alpha k}| e^{i\gamma_k} |C_{\beta k}| e^{i\phi_k} \equiv \overline{C_\alpha C_\beta} \neq 0 \quad (9)$$

Note that, in general, if γ and ϕ are not zero then the above sum is a superposition of sines and cosines that will average to zero—the random phase case.

The creation of multiple quantum coherence is equivalent to causing ρ to evolve in such a manner that $\rho_{rs} \neq 0$, and in the following discussion, we shall see how this inequality is achieved.

3 COHERENT AVERAGING

We next remind ourselves of the results of coherent averaging theory as applied to the spin portion of internal Hamiltonians.¹³ We first note that a nuclear spin Hamiltonian may, in general, be expressed as the product of a constant characteristic of the interaction in question, and of ‘spin space’ operators. For example, for the heteronuclear dipolar interaction between spins $\hat{I}$ and $\hat{S}$, the constant is $\gamma_I \gamma_S / r_{IS}^3$, the ‘real space’ portion is $1 - 3 \cos^2 \theta$, and the ‘spin space’ portion is $\hat{I}_z \hat{S}_z$. It is assumed that the real space portions of the internal Hamiltonians are constant in the experiments under consideration, i.e., there is no molecular motion or experimenter-supplied sample spinning.

When we manipulate $\hat{\mathcal{H}}_{\text{int}}$ by rf pulse sequences that are cyclic [the ensemble is returned to its initial state after a cycle of rf pulses, meaning that the propagator $\hat{U}_{\text{rf}}(t_c, 0)$ associated with the pulse train from time zero to time t_c is unity at cycle

times t_c (and integer multiples of these times)] and periodic, the leading term in the result, observed at cycle times nt_c is

$$\hat{\rho}(nt_c) = \exp(-i\hat{\mathcal{H}}_{\text{int}}^{(0)} nt_c) \hat{\rho}(0) \exp(i\hat{\mathcal{H}}_{\text{int}}^{(0)} nt_c) \quad (10)$$

where $\hat{\mathcal{H}}_{\text{int}}^{(0)}$ is the time average of a static internal Hamiltonian made time-dependent by the rf pulses:

$$\hat{\mathcal{H}}_{\text{int}}^{(0)} = \frac{1}{t_c} \int_0^{t_c} dt \hat{\mathcal{H}}_{\text{int}}(t) \quad (11)$$

$\hat{\mathcal{H}}_{\text{int}}(t)$ is the instantaneous value of the internal Hamiltonian as determined by the rf pulses:

$$\hat{\mathcal{H}}_{\text{int}}(t) = \hat{U}_{\text{rf}}^{-1}(t, 0) \hat{\mathcal{H}}_{\text{int}} \hat{U}_{\text{rf}}(t, 0) \quad (12)$$

$\hat{U}_{\text{rf}}(t, 0)$ is the propagation operator due to the rf pulses from time zero to time t . For n time intervals δ_1 , followed by δ_2 , followed by $\dots$, δ_n , $\hat{U}_{\text{rf}}$ may be expressed as the product

$$\hat{U}_{\text{rf}}(t, 0) = \hat{U}_{\text{rf}}(\delta_n) \cdots \hat{U}_{\text{rf}}(\delta_1) \quad (13)$$

whereby

$$\hat{U}_{\text{rf}}^{-1}(t, 0) = \hat{U}_{\text{rf}}^{-1}(\delta_1) \cdots \hat{U}_{\text{rf}}^{-1}(\delta_n) \quad (14)$$

Equation (12) can always be expressed as a product of rotations in spin space acting on components of angular momentum operators. For example, if the rf pulse sequence $(\tau, 180_y^\circ, \tau)$ with perfect delta function rf pulses produces $\hat{U}_{\text{rf}}$, then at times $0 \leq t \leq \tau$, when the rf Hamiltonian is zero, $\hat{U}_{\text{rf}}(t, 0)$ takes the form $e^0 = 1$, and in this time interval, $\hat{I}_z = e^0 \hat{I}_z e^0 = 1 \cdot \hat{I}_z \cdot 1$, which we may formally identify as a rotation $\hat{R}$ of unity, performed on $\hat{I}_z$, symbolized by $\hat{R}\hat{I}_z = 1 \cdot \hat{I}_z$. At time $t = \tau$, the rf Hamiltonian corresponds to an infinitely sharp 180° rotation about the y axis. $\hat{U}_{\text{rf}}(t = \tau) = \exp(i\pi\hat{I}_y)$, and the physical result is a 180_y° rotation $\hat{R}_{180y}$. For $\tau < t < 2\tau$, the rf again is zero, and $\hat{U}_{\text{rf}}$ is unity. Under this sequence, therefore, with the spin portion of $\hat{\mathcal{H}}_{\text{int}}$ being proportional to $\hat{I}_z$, keeping in mind the time ordering dictated by equations (12) and (14), we find

$$0 \leq t < \tau : \quad \hat{I}_z = 1 \cdot \hat{I}_z = \hat{I}_z \quad (15a)$$

$$t = \tau : \quad \hat{I}_z = 1 \cdot \hat{R}_{180y} \hat{I}_z = -\hat{I}_z \quad (15b)$$

$$\tau < t \leq 2\tau : \quad \hat{I}_z = 1 \cdot \hat{R}_{180y} \cdot 1 \cdot \hat{I}_z = -\hat{I}_z \quad (15c)$$

The familiar result is that at cycle times $2n\tau$, under the spin echo sequence $(\tau, 180^\circ, \tau)^n$, chemical shifts and field inhomogeneities, with spin operators $\hat{I}_{zk}$, vanish (but other interactions, such as homonuclear dipolar coupling, do not). This is to say that at cycle times $2n\tau$, with the internal Hamiltonian being proportional to $\hat{I}_z$, that $\hat{\mathcal{H}}_{\text{int}}^{(0)}$ is zero, i.e.,

$$\begin{aligned} \hat{\mathcal{H}}_{\text{cs}}^{(0)} &\sim \int_0^{2n\tau} dt \hat{U}_{\text{rf}}^{-1}(t) \hat{\mathcal{H}}_{\text{cs}} \hat{U}_{\text{rf}}(t) \\ &= \omega_{\text{cs}} [\hat{I}_z \tau + (-\hat{I}_z) \tau] = 0 \end{aligned} \quad (16)$$

where ω_{cs} is a product of a constant and the real space portion of the chemical shift Hamiltonian.

Another, perhaps less familiar, result is that under homonuclear dipolar decoupling sequences $[\tau, 90_x^\circ, \tau, 90_y^\circ, \tau]$, homonuclear dipolar terms vanish, but chemical shifts are scaled. Consider the dipolar echo sequence $[\tau, 90_x^\circ, \tau, 90_y^\circ, 2\tau, 90_y^\circ, \tau, 90_x^\circ, \tau]$. Using equations (12)–(14), we find for ideal delta function rf pulses, the following values of $\hat{I}_z(t)$:

$$0 \leq t < \tau : \quad \hat{I}_z = 1 \cdot \hat{I}_z = \hat{I}_z \quad (17a)$$

$$t = \tau : \quad \hat{I}_z \rightarrow 1 \cdot \hat{R}_{90x} \hat{I}_z = -\hat{I}_y \quad (17b)$$

$$\tau < t < 2\tau : \quad \hat{I}_z = 1 \cdot \hat{R}_{90x} \cdot 1 \hat{I}_z = -\hat{I}_y \quad (17c)$$

$$t = 2\tau : \quad \hat{I}_z \rightarrow 1 \cdot \hat{R}_{90x} \cdot 1 \cdot \hat{R}_{90y} \hat{I}_z = -\hat{I}_x \quad (17d)$$

etc., from which we may immediately infer that, the scalar product $\hat{I}_1 \cdot \hat{I}_2$ being invariant to rotation, the time dependence of the operator $\hat{\mathcal{H}}_{zz} = (\hat{I}_1 \cdot \hat{I}_2 - 3\hat{I}_{z1}\hat{I}_{z2})$ is as follows:

$$0 \leq t < \tau : \quad \hat{\mathcal{H}}_{zz} = \hat{\mathcal{H}}_{tt} \quad (17e)$$

$$t = \tau : \quad \hat{I}_{z1}\hat{I}_{z2} \rightarrow \hat{I}_{y1}\hat{I}_{y2}, \quad \text{so} \quad \hat{\mathcal{H}}_{zz} \rightarrow \hat{\mathcal{H}}_{yy} \quad (17f)$$

etc. Then the two-body average homonuclear dipolar Hamiltonian is

$$\begin{aligned} \hat{\mathcal{H}}_{\text{DII}}^{(0)} &= \frac{\omega_D}{6\tau} [\tau(\hat{I}_1 \cdot \hat{I}_2 - 3\hat{I}_{z1}\hat{I}_{z2}) + \tau(\hat{I}_1 \cdot \hat{I}_2 - 3\hat{I}_{y1}\hat{I}_{y2}) \\ &\quad + 2\tau(\hat{I}_1 \cdot \hat{I}_2 - 3\hat{I}_{x1}\hat{I}_{x2}) + \tau(\hat{I}_1 \cdot \hat{I}_2 - 3\hat{I}_{y1}\hat{I}_{y2}) \\ &\quad + \tau(\hat{I}_1 \cdot \hat{I}_2 - 3\hat{I}_{z1}\hat{I}_{z2})] \\ &\equiv \frac{1}{3}\omega_D(\hat{\mathcal{H}}_{zz} + \hat{\mathcal{H}}_{yy} + \hat{\mathcal{H}}_{xx}) = 0 \end{aligned} \quad (18)$$

where ω_D is a product of a constant and the real space portion of the space-spin product dipolar Hamiltonian.

An important result just seen is that the sum

$$(\hat{\mathcal{H}}_{xx} + \hat{\mathcal{H}}_{yy} + \hat{\mathcal{H}}_{zz})\tau = \sum_k \hat{\mathcal{H}}_{kk} = 0 \quad (19)$$

for two spins $\mathbf{I}_1$ and $\mathbf{I}_2$. In both of the above cases, the average Hamiltonian for a specific interaction is made to vanish, leaving remaining interactions to be observed. However, it is possible to manipulate certain internal interactions such that the average Hamiltonian is not zero, but something else that we want.

4 DEVELOPMENT OF MULTIPLE QUANTUM COHERENCE: USE OF A DOUBLE QUANTUM PROPAGATOR

What do we want as an average Hamiltonian in order to develop multiple quantum coherence? The answer is an average Hamiltonian that allows the density operator at zero

time $\hat{\rho}(0)$ to evolve in such a manner that $\hat{\rho}_{1,1\pm k} \neq 0$, where k is the order of the multiple quantum coherence.

The process, then, is to manipulate some internal Hamiltonian with cyclic, periodic rf pulses such that at cycle times nt_c , we have an average Hamiltonian that allows a zero-time equilibrium density operator,

$$\hat{\rho}(0) \equiv \hat{\rho}_{\text{eq}} \sim \sum_i \hat{I}_{zi}, \quad i = 1, 2, \dots \quad (20)$$

containing only diagonal terms representing populations in the Zeeman basis set, to develop MQC, i.e., to develop in such a manner that $\hat{\rho}_{i,i\pm k} \neq 0$, for $1 \leq k < \infty$. Since we can only detect single quantum coherence (SQC) with NMR, we note in advance that once produced, the MQC must be reduced to SQC in a manner that reflects the MQC therein contained in order to be detected.

Examples of terms in the density operator that exhibit SQC might be single spin terms $\hat{I}_i^+$ and $\hat{I}_i^-$, or two-spin products of the form $\hat{I}_1^+ \hat{I}_2^-$. Double quantum coherence is represented by two-spin product terms in the density operator such as $\sum_{ij} (\hat{I}_i^+ \hat{I}_j^+ + \hat{I}_i^- \hat{I}_j^-)$. Triple quantum coherence would be represented by three-spin products such as $\hat{I}_j^+ \hat{I}_k^+ \hat{I}_m^+$.

We can understand how this process works by example. An ensemble of spin- $\frac{1}{2}$ systems (e.g., protons in solid adamantane) is allowed to come to equilibrium in a static field for a time that is long compared with T_1 . Then

$$\hat{\rho}(0) \sim \sum_i \hat{I}_{zi} \quad (21)$$

The sum is over all spins in the sample. Under the influence of an average Hamiltonian, produced by coherent averaging in spin space, as discussed for the cases of the spin echo and the dipolar echo, this ensemble is allowed to evolve over time. The formal time evolution formula may be expressed in terms of the product

$$f(\hat{A}, \hat{B}) = e^{\hat{A}} \hat{B} e^{-\hat{A}} \quad (22)$$

where $\hat{A}$ and $\hat{B}$ are operators.

It may be shown (equation (4.19) in Gerstein and Dybowski¹³) that an equivalent form of this product is

$$\begin{aligned} e^{\hat{A}} - \hat{B} e^{-\hat{A}} &= \hat{B} + [\hat{A}, \hat{B}] + [\hat{A}, [\hat{A}, \hat{B}]]/2! \\ &\quad + [\hat{A}, [\hat{A}, [\hat{A}, \hat{B}]]]/3! + \dots \end{aligned} \quad (23)$$

i.e.,

$$\hat{\rho}(nt_c) \sim \exp(-i\hat{\mathcal{H}}nt_c) \sum_i \hat{I}_{zi} \exp(i\hat{\mathcal{H}}nt_c) \quad (24)$$

and

$$\begin{aligned} \rho(nt_c) &= \sum_i \hat{I}_{zi} + \left[-int_c \hat{\mathcal{H}}, \sum_i \hat{I}_{zi} \right] \\ &\quad + \left[-int_c \hat{\mathcal{H}}, \left[-int_c \hat{\mathcal{H}}, \sum_i \hat{I}_{zi} \right] \right] / 2! + \dots \end{aligned} \quad (25)$$

The leading term $\sum_i \hat{I}_{zi}$ represents populations. The following terms must then be arranged so as to evolve single and higher quantum coherences.

In order to understand how to choose an average Hamiltonian that will produce multiple quantum coherence in the time-developed density operator $\hat{\rho}(t)$ as given by equation (25), it is necessary to look at the commutation rules for angular momentum operators. We know that

$$[\hat{I}_{k1}, \hat{I}_{k2}] = [\hat{I}_{k1}, \hat{I}_{k1}] = 0, \quad k = x, y, z \quad (26a)$$

$$[\hat{I}_z, \hat{I}^\pm] = \pm \hat{I}^\pm \quad (26b)$$

$$[\hat{I}^\pm, \hat{I}^\pm] = \pm 2\hat{I}_z \quad (26c)$$

$$[\hat{I}^\pm, \hat{I}^\pm] = 0 \quad (26d)$$

Given the form of $\hat{\rho}_{\text{eq}} \equiv \hat{\rho}(0) \sim \sum_i \hat{I}_{zi}$, equations (24) and (26a)–(26d) immediately tell us that we want $\hat{\mathcal{H}}$ to contain terms such as $\hat{I}_i^+$. Since we are using the internal homonuclear dipolar coupling Hamiltonian $\hat{\mathcal{H}}_{zz}$ as that which is to be manipulated in order to develop the multiple quantum coherence according to equation (27), we realize that we shall always be dealing with products between spins 1 and 2 containing terms such as $\hat{I}_{m1}\hat{I}_{m2}$, with $m = x, y, z$.

To begin to think about how rotations in spin space affect the two-body homonuclear dipolar Hamiltonian $\hat{\mathcal{H}}_{zz}$, it is useful to remember¹³ that the effect of a rotation of the m th component of angular momentum, $\hat{I}_m$ by the operation

$$\begin{aligned} \hat{R}_j(\theta) \hat{I}_m &= \exp(i\theta \hat{I}_j) \hat{I}_m \exp(-i\theta \hat{I}_j) \\ &= \hat{I}_m \cos(\theta \epsilon_{jmp}) - \hat{I}_p \sin(\theta \epsilon_{jmp}) \end{aligned} \quad (27)$$

where ϵ_{jmp} is zero if any two of j, m , and p are the same, unity if j, m , and p represent some cyclic order of x, y , and z , and -1 if the order is anticyclic. Then a result found after some algebra is that a rotation of the two-body Hamiltonian for spins 1 and 2, $\hat{\mathcal{H}}_{zz}$, by ξ about the y axis, followed by a rotation by ϕ about the z axis, yields

$$\begin{aligned} \hat{R}_z(\phi) \hat{R}_y(\xi) \hat{\mathcal{H}}_{zz} &= \frac{1}{2} \omega_D (3 \cos^2 \xi - 1) \hat{\mathcal{H}}_{zz} \\ &\quad - \frac{3}{2} \omega_D (\hat{I}_{z1} \hat{I}_2^+ + \hat{I}_1^+ \hat{I}_{z2}) e^{-i\phi} \sin \xi \cos \xi \\ &\quad + \frac{3}{2} \omega_D (\hat{I}_1^+ \hat{I}_2^+ e^{2i\phi} + \hat{I}_1^- \hat{I}_2^- e^{-2i\phi}) \\ &\quad \times \sin^2 \xi \end{aligned} \quad (28)$$

The interesting result shown by equation (28) is that a general rotation of $\hat{\mathcal{H}}_{zz}$ in spin space yields a propagator (the exponential of the rotated Hamiltonian) containing populations ($\hat{\mathcal{H}}_{zz}$), single quantum terms ($\hat{I}_1^\pm \hat{I}_{z2}$) and double quantum terms ($\hat{I}_1^\pm \hat{I}_2^\pm$). As a special case of this result, we illustrate the formation of a two-quantum propagator under a particularly simple periodic and cyclic sequence.¹¹ This is the sequence $(\tau, 90^\circ_x, 4\tau, 90^\circ_{\bar{x}}, \tau)$, which we shall denote by $x, \bar{x}$. We assume ideal delta function pulses. Under this sequence, the operator $\hat{I}_z(t)$ is as follows:

$$0 \leq t < \tau : \quad \hat{I}_z = 1 \cdot \hat{I}_z = \hat{I}_z \quad (29a)$$

$$t = \tau : \quad \hat{I}_z = \hat{R}_{90x} \hat{I}_z = -\hat{I}_y \quad (29b)$$

$$\tau < t < 5\tau : \quad \hat{I}_z = -\hat{I}_y \quad (29c)$$

$$t = 5\tau : \quad \hat{I}_z = \hat{R}_{90x} \cdot 1 \cdot \hat{R}_{90x} \hat{I}_z = \hat{I}_z \quad (29d)$$

$$5\tau < t \leq 6\tau : \quad \hat{I}_z = \hat{I}_z \quad (29e)$$

Then, for example, in the time interval $0 \leq t < \tau$, $\hat{\mathcal{H}}_{zz} = \hat{\mathcal{H}}_{zz}$ [see equation (12)]. From an observation of the values of $\hat{I}_z(t)$, and the recognition that $\hat{\mathcal{H}}_{kk}$ contains the product $\hat{I}_k \hat{I}_k$ with $k = x, y, z$, it is possible to infer the values of $\hat{\mathcal{H}}_{zz}(t)$, immediately, and thus to calculate the average Hamiltonian corresponding to $\hat{\mathcal{H}}_{zz}$ to zeroth order:

$$\hat{\mathcal{H}}_{zz}^{(0)} = \frac{1}{6\tau} \int_0^{6\tau} dt \hat{\mathcal{H}}_{zz} = \frac{1}{3} (\hat{\mathcal{H}}_{zz} + 2\hat{\mathcal{H}}_{yy}) \quad (30)$$

With the identity $\sum_k \hat{\mathcal{H}}_{kk} = 0$, we find that, under the above sequence,

$$\hat{\mathcal{H}}_{zz}^{(0)} \simeq (\hat{\mathcal{H}}_{xx} \hat{\mathcal{H}}_{yy} + 2\hat{\mathcal{H}}_{yy}) = \hat{\mathcal{H}}_{yy} - \hat{\mathcal{H}}_{xx} \quad (31)$$

The reader will want to verify that under the sequence $y, \bar{y} \equiv (\tau, 90^\circ_y, 4\tau, 90^\circ_{\bar{y}}, \tau)$ the average homonuclear dipolar Hamiltonian is the negative of that found in equation (31), i.e. is proportional to $\hat{\mathcal{H}}_{xx} - \hat{\mathcal{H}}_{yy}$. Thus this sequence can be used to produce an average Hamiltonian that will act to reverse, in time, the effect of the average of the average Hamiltonian $\hat{\mathcal{H}}_{yy} - \hat{\mathcal{H}}_{xx}$ that was used to produce the MQC. As will be seen, this reconversion is performed in such a manner that the information content associated with the MQC is not lost. The means of doing so (see below) is to phase-shift the two quantum excitation sequence $x, \bar{x}$ with respect to the two quantum reconversion sequence $y, \bar{y}$ in steps of $2\pi/k_{\text{max}}$, where k_{max} is the highest order of MQC to be observed.

With $\hat{I}^\pm = \hat{I}_x \pm i\hat{I}_y$, we find that the average two-body homonuclear dipolar Hamiltonian under the two quantum excitation sequence $x, \bar{x}$ is proportional to

$$\hat{I}_1^+ \hat{I}_2^+ + \hat{I}_1^- \hat{I}_2^- \quad (32)$$

for the pair of spins I_1 and I_2 .

Now consider how this sequence can be used to develop multiple quantum coherence for an ensemble of *pairs* of dipolar coupled spins I_1 and I_2 . We might anticipate in advance that for this simple case, using a two quantum propagator, all that will be seen are populations, and two quantum coherence. Under this sequence, repeated for n cycle times, $\tau_c = 6\tau$, the time dependence of the density matrix becomes

$$\hat{\rho}(nt_c) = \hat{U}_{2Q} \hat{\rho}(0) \hat{U}_{2Q}^{-1} \quad (33)$$

where $\hat{U}_{2Q}$ is, to zeroth order,

$$\hat{U}_{2Q} = \exp[-\frac{1}{2} int_c \omega_D (\hat{I}_1^+ \hat{I}_2^+ + \hat{I}_1^- \hat{I}_2^-)] \quad (34)$$

Then, with $\theta = \frac{1}{2} nt_c \omega_D$, equations (24) and (25) yield

$$\begin{aligned} \hat{\rho}(nt_c) &\simeq \hat{I}_{z1} + \hat{I}_{z2} + i\theta [\hat{I}_1^+ \hat{I}_2^+ + \hat{I}_1^- \hat{I}_2^-, \hat{I}_{z1} + \hat{I}_{z2}] \\ &\quad + (i\theta)^2 [\hat{I}_1^+ \hat{I}_2^+ + \hat{I}_1^- \hat{I}_2^-, [\hat{I}_1^+ \hat{I}_2^+ + \hat{I}_1^- \hat{I}_2^-, \hat{I}_{z1} + \hat{I}_{z2}]]/2! + \dots \\ &= \hat{I}_{z1} + \hat{I}_{z2} - 2i\theta (\hat{I}_1^+ \hat{I}_2^+ + \hat{I}_1^- \hat{I}_2^-) \end{aligned} \quad (35)$$

Figure 1 Selection rule for an n -spin operator after excitation with a double quantum propagator. The allowed values are $k = \pm 2, \pm 6, \dots$, for n even, and $k = 0, \pm 4, \pm 8, \dots$, for n odd

Only the first two terms in the series represented by equations (24) and (25) are nonzero. The remaining terms vanish. Only populations and double quantum coherence remains. At values of θ near zero, i.e., at times nt_c that are small compared with the inverse of the dipolar linewidth ω_D^{-1} , there exist only populations. As nt_c becomes of the order of the dipolar linewidth, two quantum coherence makes its appearance. No more than two quantum coherence is ever seen, regardless of how long the system is allowed to evolve, as one would physically expect from an ensemble consisting of coupled pairs of spins $\frac{1}{2}$. The reader will want to verify that for this representation of $\hat{\rho}(nt_c)$ only the terms $\rho_{11}, \rho_{22}, \rho_{33}, \rho_{13}$, and ρ_{31} are nonzero within the triplet basis set $|I, I_z\rangle$:

$$|m\rangle = |3\rangle = |1, 1\rangle = |\alpha\alpha\rangle \quad (36a)$$

$$|m-1\rangle = |2\rangle = |1, 0\rangle = \sqrt{\frac{1}{2}}|\alpha\beta + \beta\alpha\rangle \quad (36b)$$

$$|m-2\rangle = |1\rangle = |1, -1\rangle = |\beta\beta\rangle \quad (36c)$$

by performing the calculations $\langle m|\hat{\rho}(nt_c)|m-k\rangle$.

The results just calculated for an ensemble of dipolar coupled spin- $\frac{1}{2}$ pairs indicate that, under the propagator $\hat{U}_{2Q}$ developed by the sequence $(\tau, 90^\circ_x, 4\tau, 90^\circ_{\bar{x}}, \tau)$, the selection rules are such that populations and double quantum coherence is observed for an ensemble of pairs of dipolar coupled spins $\frac{1}{2}$. More generally, these selection rules for ensembles of n coupled spins may be exhibited by the diagram shown in Figure 1. This diagram states that, under this sequence, double quantum coherence will be exhibited by ensembles of 2, 4, 6, ... coupled spins, four quantum coherence will be exhibited by ensembles of 5, 7, 9, ... coupled spins, etc.

5 DETECTION OF MULTIPLE QUANTUM COHERENCE

We must now consider more closely what was meant by the past statement that the MQC, once produced, must be transferred to SQC in a manner that reflects the MQC previously produced. As a thought experiment to begin the process, recall the inversion-recovery experiment for measuring T_1 . In this case, the system is prepared in a state of

Figure 2 Time evolution of the order of n quantum coherence using a single quantum propagator. The intensity of (I_0) decreases as spin pairs begin to couple to develop the higher order of MQC and build up their intensity (I_1 and I_2)

nonequilibrium populations by an inverting 180° pulse. After a time τ , during which the system is allowed to evolve under ' T_1 processes', these populations are converted into SQC using a 90° pulse. The initial intensity of the decay after the 'readout' 90° pulse is used, as a function of τ , to calculate T_1 . A similar reasoning applies to detecting MQC. The MQC is developed as a function of multiples of the production sequence cycle time t_c . This development is only observable if it is converted into SQC. During the development, therefore, the MQC is manipulated in such a manner that, when converted back into SQC, the information content of the MQC is contained in the initial intensity of the SQC which is detected.

To form a picture of how this works, it is useful to think about how the different orders of n quantum coherence evolve with time. As indicated in the example in equation (35), the higher orders of MQC develop as $\theta \approx nt_c\omega_{Dij}$ increases for the i,j th pair of spins. Therefore, it seems reasonable that the evolution of, e.g., populations, SQC, and two-quantum coherence (DQC) might look as shown in Figure 2. I_0 represents populations, I_1 the intensity of single quantum coherence, I_2 the intensity of DQC, etc. Initially, one starts with populations. As spin pairs begin to couple to form higher orders of n quantum coherence, there is a net loss in populations, and a build up [in the particular example for which the calculation using equation (35) was made], first of DQC, the second term in the expansion of the evolution of $\hat{\rho}$, and then of higher orders of MQC as time increases. In the example shown in Figure 2, we assume that we are allowed to build MQC in steps of single quanta, and we shall later provide a single quantum propagator $\hat{U}_{1Q}$ that allows this development to be performed.

Given the development of MQC shown in Figure 2, caused by the single quantum propagator $\hat{U}_{1Q}$, it is simple to conceive how one reverses the process to convert back to an observable SQC. One simply causes the system to evolve under the propagator $\hat{U}_{1Q}^{-1}$. Since $\hat{U}_{1Q}$ will be of the form $\exp(-i\hat{\mathcal{H}}nt_c)$, with $\hat{\mathcal{H}}$ being an average Hamiltonian created by manipulating the homonuclear dipolar interaction, time reversal is achieved by manipulating the homonuclear dipolar Hamiltonian such that from time nt_c to $2nt_c$ the average Hamiltonian is $-\hat{\mathcal{H}}$. In the case of the two quantum propagator, we have seen that the sequence $(\frac{1}{4}\tau, 90^\circ_x, \tau, 90^\circ_{\bar{x}}, \frac{1}{4}\tau)$ produces the average Hamiltonian proportional to $\hat{\mathcal{H}}_{yy} - \hat{\mathcal{H}}_{xx}$. We have pointed out that the sequence $(\frac{1}{4}\tau, 90^\circ_y, \tau, 90^\circ_{\bar{y}}, \frac{1}{4}\tau)$ results in

Figure 3 The MQC for higher orders are first created over a time period nt_c , and then collected this MQC back into ZQC at the time $2nt_c$ by using the negative of the average Hamiltonian. Aside from relaxation, the preparation ($0 \leq t < nt_c$) and mixing period ($nt_c \leq t < 2nt_c$) exactly mirror each other. This diagram illustrates the statement of the cyclic properties of $\hat{U}_{rf}$. At the end of $2nt_c$, $I_0(t=0) = I_0(t=2nt_c)$

the average homonuclear dipolar Hamiltonian $\hat{\mathcal{H}}_{xx} - \hat{\mathcal{H}}_{yy} \equiv -(\hat{\mathcal{H}}_{yy} - \hat{\mathcal{H}}_{xx})$. Thus, the application of the sequence

$$(\frac{1}{4}\tau, 90^\circ_x, \tau, 90^\circ_x, \frac{1}{4}\tau)n, (\frac{1}{4}\tau, 90^\circ_y, \tau, 90^\circ_y, \frac{1}{4}\tau)n$$

would first create the MQC over a time of n cycle times t_c , and then, by time reversal accomplished by using the negative of the average Hamiltonian during the preparation period, ‘collect’ this MQC back into zero quantum coherence (ZQC) at time $2nt_c$. The process might be visualized as indicated in Figure 3.

At this point, however, there is no information content in the ZQC shown in Figure 3 at time $2nt_c$ that would be indicative of the MQC created during the times nt_c .

Therefore, as a second thought experiment, dictated by the knowledge that different orders of MQC (see below) oscillate at multiples of the SQC under a frequency offset, let us assume that after the production period nt_c , a frequency offset δ (in Hz) is imposed upon the experiment. Then the behavior of ZQC, SQC, and DQC might appear as indicated in Figure 4. The ZQC does not oscillate under an offset. The SQC will oscillate with period δ^{-1} . The DQC will oscillate with period $(2\delta)^{-1}$, etc.

Now suppose that the evolution time for MQC under the offset δ were set to be $(2\delta)^{-1}$. Then at that time I_1 would be zero, I_0 would retain its value at time $t = nt_c$, and I_2 would have oscillated to its value at time $(2\delta)^{-1}$, the period of its oscillation. Therefore, if the reconversion from nonvanishing off-diagonal elements of the density operator back to populations represented by diagonal elements were initiated at time $nt_c + (2\delta)^{-1}$, in the absence of an offset, the value of I_0 at time $2nt_c + (2\delta)^{-1}$ would contain *no contribution* from the SQC. The SQC monitored as the value of the initial intensity of the FID after a 90° pulse at time $nt_c + (2\delta)^{-1}$ would therefore be lower than that in the absence of an offset. One way of visualizing this result is shown in Figure 5, where different symbols are used to trace the imagined evolution of MQC back into populations after time $nt_c + (2\delta)^{-1}$. The symbol I_n , $n \geq 1$, means the n quantum coherence. The symbol I_n^0 means the contribution of the n quantum coherence developed at time $nt_c + (2\delta)^{-1}$ back into populations. The net

Figure 4 The behavior of ZQC, SQC, and DQC with a frequency offset δ (in Hz), after the preparation period nt_c . The n quantum coherence has the property of the cosine function, $I_n \propto \cos(n\delta/\text{Hz})$. See equation (42)

Figure 5 The behavior of the MQC at the evolution time $(2\delta)^{-1}$. I_0/k is the development of ZQC with k quantum coherence as its parent

magnetization associated with population differences, observed as the initial intensity of the FID after a ‘readout’ pulse converting population differences into SQC, is labeled I_0^{tot} . Clearly, I_0^{tot} will oscillate with time under a frequency offset during the evolution period, and this oscillation provides the means of detecting MQC therein contained, as indicated more analytically below.

The scheme of production and reconversion of MQC corresponding to the time development shown in Figure 3, i.e., in the absence of an offset, meaning in the absence of an evolution period, is indicated in Figure 6; a single quantum propagator acts on the ensemble of coupled spins from time zero to time nt_c , and the inverse of that propagator acts for an equal period of time afterwards. The ZQC at time $2nt_c$ is converted into observable SQC by a 90° ‘readout’ pulse, and is represented by the initial value of the FID. In the absence of irreversibility, the initial amplitude of the FID detected at time $2nt_c$ will be the same as that detected at time zero after a ‘readout’ 90° pulse. The equality of these two amplitudes, incidentally, is one means of detecting one’s ability to perform time reversal effectively, which is a measure of the perfection of the pulse sequences used.

Figure 6 The scheme of a two-dimensional NMR pulse sequence, composed of preparation, evolution, mixing and detection periods, is adapted to develop multiple quantum coherence. The evolution period is set at zero

The imposition of a frequency offset δ during the evolution period, to detect MQC at the end of the mixing period, is not without its problems. One problem is that there is irreversible time evolution of the ensemble during the evolution period due to T_2 processes. A means of avoiding this problem is to realize that imposition of a phase shift¹⁴ ϕ during the preparation period $0 \leq t < nt_c$ is formally equivalent to imposition to a frequency offset, and causes the same oscillations of the various orders of MQC as would be observed under a frequency offset. The effect of a phase increment during the preparation period on the detected signal intensity at the end of the mixing period is now considered. In the absence of an evolution period, the initial intensity of the FID detected at the end of the mixing period $t = 2nt_c$ is

$$\langle \hat{I}_z(t = 2nt_c) \rangle = \text{Tr}\{\hat{\rho}(t = 2nt_c) \hat{I}_z\} \quad (37)$$

But

$$\hat{\rho}(2nt_c) = \hat{U}_{1Q}^{-1} \hat{U}_{1Q} \hat{I}_z \hat{U}_{1Q}^{-1} \hat{U}_{1Q} = \langle \hat{I}_z(t = 0) \rangle \quad (38)$$

in the absence of irreversibility due to imperfections, and interactions other than homonuclear dipolar coupling. Looking more carefully at the combination of equations (37) and (38), and leaving the subscript off the propagators $\hat{U}$ for simplicity, we find that

$$\begin{aligned} \langle \hat{I}_z(t = 2nt_c) \rangle &= \text{Tr}\{\hat{U}^{-1} \hat{U} \hat{I}_z \hat{U}^{-1} \hat{U} \hat{I}_z\} \\ &= \text{Tr}\{\hat{U} \hat{I}_z \hat{U}^{-1} \hat{U} \hat{I}_z \hat{U}^{-1}\} \\ &= \sum_r \langle r | \hat{U} \hat{I}_z \hat{U}^{-1} \hat{U} \hat{I}_z \hat{U}^{-1} | r \rangle \\ &= \sum_{r,s} \langle r | \hat{U} \hat{I}_z \hat{U}^{-1} | s \rangle \langle s | \hat{U} \hat{I}_z \hat{U}^{-1} | r \rangle \\ &= \sum_{r,s} |\langle r | \hat{U} \hat{I}_z \hat{U}^{-1} | s \rangle|^2 \end{aligned} \quad (39)$$

Equation (39) has an interesting interpretation. The quantity $\hat{U}(nt_c, 0) \hat{I}_z \hat{U}^{-1}(nt_c, 0)$ measures how much multiple quantum coherence has been developed under the propagator $\hat{U}$. The quantity $\langle r | \hat{U} \hat{I}_z \hat{U}^{-1} | s \rangle$ measures the k quantum coherence, where $k = r - s$, as described earlier, and as will be again illustrated shortly. The term $|\langle r | \hat{U} \hat{I}_z \hat{U}^{-1} | s \rangle|^2$ is the intensity of the k quantum coherence. Thus the quantity detected as the SQC by a proper ‘readout’ pulse at time $t = 2nt_c$ is the result of producing multiple quantum coherence under a propagator $\hat{U}$ acting for a time $t = nt_c$, and converting this coherence

Figure 7 The arrangement of pulse sequence and the way of phase shifting during the multiple quantum experiment. The phases only of the pulses in the preparation period are shifted at the same time with the aid of a digital phase shifter, while the phases of the pulses in the mixing period remain unchanged

back into populations via the inverse propagator $\hat{U}^{-1}$ during an equal time nt_c .

Now we need to ask: ‘What is the effect of a phase change ϕ imposed on all of the pulses during the preparation period, but not on the pulses during the mixing period, at the total evolution time $t = 2nt_c$?’ In this experiment, the ‘evolution period’ identified as the time between the preparation and mixing periods, is zero. A phase change ϕ is effected by physically rotating all excitation pulses during the preparation period by ϕ . This means that a 180°_x pulse, for example, becomes $180^\circ_{x+\phi}$, and a $180^\circ_{\bar{x}}$ pulse becomes $180^\circ_{\bar{x}+\phi}$, etc. The operator form of $\hat{U}$ rotated by ϕ is just $\hat{U}_\phi = \exp(-i\phi) \hat{I}_z \hat{U} \exp(i\phi \hat{I}_z)$. The experimental arrangement is indicated in Figure 7.

The expectation value of $\hat{I}_z$ detected at times $t = 2nt_c$ will be dependent upon ϕ , as follows:

$$\begin{aligned} \langle \hat{I}_z(\phi, 2nt_c) \rangle &= \text{Tr}\{\hat{U}(2nt_c, 0) \hat{\rho}(0) \hat{U}^{-1}(2nt_c, 0) \hat{I}_z\} \\ &= \text{Tr}\{\hat{U}_{\phi=0}^{-1}(2nt_c, nt_c) \hat{U}_\phi(nt_c, 0) \hat{I}_z \hat{U}_\phi^{-1}(nt_c, 0) \\ &\quad \times \hat{U}_{\phi=0}(2nt_c, nt_c) \hat{I}_z\} \\ &\equiv \text{Tr}\{\hat{U}_0^{-1} \hat{U}_\phi \hat{I}_z \hat{U}_\phi^{-1} \hat{U}_0 \hat{I}_z\} \\ &= \sum_{r,s} \langle r | \exp(-i\phi \hat{I}_z) \hat{U} \exp(i\phi \hat{I}_z) \hat{I}_z \\ &\quad \times \exp(-i\phi \hat{I}_z) \hat{U}^{-1} \exp(i\phi \hat{I}_z) | s \rangle \langle s | \hat{U} \hat{I}_z \hat{U}^{-1} | r \rangle \\ &= \sum_{k=r-s} e^{-ik\phi} |\langle r | \hat{U} \hat{I}_z \hat{U}^{-1} | s \rangle|^2 \end{aligned} \quad (40)$$

We have noted that the quantity $\hat{U} \hat{I}_z \hat{U}^{-1}$ represents the time development of $\hat{I}_z$ under the propagator $\hat{U}$, in this case a propagator developing MQC. Nonzero values of $\langle r | \hat{U} \hat{I}_z \hat{U}^{-1} | s \rangle$ indicate nonzero values of $r - s = k$ quantum coherence $|\langle r | \hat{U} \hat{I}_z \hat{U}^{-1} | s \rangle|^2$ is the intensity of the k quantum coherence.

The result,

$$\langle \hat{I}_z(\phi, 2nt_c) \rangle = \sum_{k=-\infty}^{\infty} e^{-ik\phi} |\langle r | \hat{U} \hat{I}_z \hat{U}^{-1} | s \rangle|^2 \quad (41)$$

may be compared with the value of the free precession decay of a system containing an ensemble of spins oscillating with intensities A_n at frequencies ω_n with some phase ϕ_n with respect to the phase of detection, chosen to be y for the present example:

$$G(t) = \langle \hat{I}_y(t) \rangle = \sum_n A_n \cos(\omega_n t + \phi_n) \quad (42)$$

The FT to the frequency domain reveals the frequency content of $G(t)$ which, with appropriate phase correction, becomes the frequency spectrum $G(\omega) = F^{-1}G(t)$. By direct analogy, the result (equation (41)) is the superposition in the phase domain $G(\phi)$ of oscillations with intensities $A_k = \langle r | \hat{U}_z \hat{U}^{-1} | s \rangle|^2$, and oscillations in the ϕ domain specified by k :

$$G(\phi) = \sum_k A_k \cos(k\phi + \delta_k) \quad (43)$$

The ϕ dependence is experimentally mapped by incrementing the phase of all pulses during the preparation period by $\Delta\phi$, in a series of m experiments at fixed preparation and mixing periods nt_c , and observing the initial value of the FID following a 90° sampling pulse immediately after $t = 2nt_c$. In practice the signal-to-noise ratio is increased if the entire on-resonant decay is integrated from a period after the receiver has recovered from the overload of the 90° pulse until no further signal is present. For strongly dipolar coupled systems with a properly operating solid state spectrometer operating at, say, 220 MHz for protons, this means a dead time of about $3 \mu s$, and an integration period of less than $1 \mu s$.

The k dependence of $G(\phi)$ is determined from the ϕ FT. Though it is not obvious from the above discussion, $G(\phi)$ is symmetric in k , so only the cosine transform is needed:

$$G(k) = \frac{1}{\sqrt{2\pi}} \int_0^\infty d\phi G(\phi) \cos k\phi \quad (44)$$

Therefore, both positive and negative coherences are detected simultaneously. One need use $k_{\max}$ phase shifts $\delta\phi_i$,

$$0 \leq \delta\phi_i \leq \pi \quad (45)$$

in steps $\Delta\phi = \pi/k_{\max}$ to obtain all of the information necessary for the production of a multiple quantum spectrum $G(k)$ versus k , via Fourier transformation of the oscillatory signal $G(\phi)$ collected from the initial values of the FIDs after the multiple quantum production and collection sequences (i.e., after the preparation and mixing periods). This is to say that to see a multiple quantum spectrum $G(k)$ versus k , with k extending to $k_{\max}$, one carries out $n = k_{\max} + 1$ experiments with phase shifts $\Delta\phi_1 = 0, \Delta\phi_2 = \pi/k_{\max}, \Delta\phi_3 = 2\pi/k_{\max}, \dots, \Delta\phi_n = \pi$. In the absence of irreversibility, the value of $G(\phi)$ versus ϕ is symmetric about $\phi = \pi$. Therefore the values of $G(\phi)$ in the range $\pi < \phi \leq 2\pi$ are obtained from the data in the range $0 \leq \phi \leq \pi$; i.e. $G(2\pi) = G(0)$, $G(2\pi - \pi/k_{\max}) = G(\pi/k_{\max})$, etc. A suitably large number (e.g., 100) of periods of $G(\phi)$ versus ϕ are then stored as an array that can be apodized by the function $e^{-a\phi}$ and Fourier transformed on ϕ to produce the multiple quantum spectrum $G(k)$ versus k . This spectrum will show peaks differing by units of 2 quanta each if a two quantum propagator is used, or in steps of one quantum each if a single quantum (see below) is used.

The selection rules for exciting single quantum coherence are shown in Figure 8. With the system prepared only as polarization ($I_z \neq 0$), two coupled spins ($n = 2$) will contribute single quantum coherence and zero quantum coherence, three coupled spins will contribute zero and double quantum coherence, etc.

An example of experimental data obtained for $G(\phi)$, with $0 \leq \phi \leq 2\pi$, using a single quantum propagator on adamantane,

Figure 8 Selection rules for the single quantum propagator used in this work

Figure 9 The intensity changes with the phase increment ($\Delta\phi = 22.5^\circ$) of the preparation pulses, plotted in the phase domain (adamantane). The FID of each phase is transformed to frequency domain, and each point on the plot is obtained by integrating the whole spectrum area, normally from -50 kHz to 50 kHz

with phase increments chosen so as to see $k_{\max} = 8$ and with $312 \mu s$ of excitation time, is shown in Figure 9. These points repeated 128 times to fit to 2K size, and tapered by an appropriate apodization function, are shown in Figure 10. The baseline decay represents populations, so it may be subtracted from the oscillations shown in Figure 10 using a baseline adjustment technique before performing the transform on ϕ to yield the multiple quantum spectrum shown in Figure 11. Note that the zero quantum peak is not present in this spectrum.

We now discuss the development of multiple quantum coherence using a single quantum propagator.

6 A SINGLE QUANTUM PROPAGATOR

The development of MQC under pulse sequences resulting in a single quantum propagator for dipolar coupled spin- $\frac{1}{2}$ systems was first reported and discussed by Suter et al.¹⁵ in 1987. The sequence that we have used to produce the data shown in Figures 9–11 was developed by M. Goldman,¹⁶ and is essentially identical to that published in 1988 by the Pines group.¹⁷

Figure 10 An extension of data point and tapering are performed to generate a data set in the phase domain. Figure 9 was repeated until the number of data points was 2K, and then tapered by using an appropriate apodization function

Figure 11 The Fourier transformed spectrum, from phase domain to multiple quantum number domain. The intensity distribution over the multiple quantum number $k = 8$ can be seen. The preparation time was $260 \mu\text{s}$. The highest number of quanta k_{max} is not seen, due to the increment of the phase used

This sequence is shown in Figure 12. Important to understanding how this sequence works is an understanding of the development of internal Hamiltonians during finite pulses, an example of which is in Chapter 5, Section V of Pines⁸ for the case of the ‘flip-flop’ phase tuning sequence (τ , 90°_x , τ , $90^\circ_{\bar{x}}$, τ). Applied to the sequence of Figure 12, the calculation proceeds as follows: consider the time interval $0 \leq t < \frac{1}{4}\tau$. Immediately after a perfect delta function rotation by 45°_x at $t = 0$, $\hat{\mathcal{H}}_{zz}$ will be

$$\hat{R}_x(45^\circ)\hat{\mathcal{H}}_{zz} = \frac{1}{2}(\hat{\mathcal{H}}_{zz} + \hat{\mathcal{H}}_{yy}) - \frac{3}{2}(\hat{I}_{z1}\hat{I}_{y2} + \hat{I}_{y1}\hat{I}_{z2}) \quad (46)$$

The contribution to $\hat{\mathcal{H}}_{zz}^{(0)}$ for this period will then be

$$\frac{1}{t_c} \int_0^{\tau/4} \hat{\mathcal{H}}_{zz} dt = \frac{1}{t_c} \frac{\tau}{8} [\hat{\mathcal{H}}_{zz} + \hat{\mathcal{H}}_{yy} - 3(\hat{I}_{z1}\hat{I}_{y2} + \hat{I}_{y1}\hat{I}_{z2})] \quad (47)$$

Figure 12 Pulse sequence for the single quantum propagator developed by Goldman,¹⁶ and used in this work

During the period $\frac{1}{4}\tau \leq t < \frac{5}{4}\tau$,

$$\begin{aligned} \hat{\mathcal{H}}_{zz}(t) &= \hat{R}_{45x} \hat{R}_{\xi y} \hat{\mathcal{H}}_{zz} \\ &= \hat{R}_{45x} \{ \hat{I}_1 \cdot \hat{I}_2 - 3[\hat{I}_{z1}\hat{I}_{z2} \cos^2 \xi + \hat{I}_{x1}\hat{I}_{x2} \sin^2 \xi \\ &\quad + (\hat{I}_{z1}\hat{I}_{x2} + \hat{I}_{x1}\hat{I}_{z2}) \sin \xi \cos \xi] \} \\ &= \hat{I}_1 \cdot \hat{I}_2 - \frac{3}{2} \{ (\hat{z}_1\hat{z}_2 + \hat{y}_1\hat{y}_2 + \hat{z}_1\hat{y}_2 + \hat{y}_1\hat{z}_2) \cos^2 \xi \\ &\quad + 2\hat{x}_1\hat{x}_2 \sin^2 \xi \\ &\quad + \sqrt{2}[(\hat{z}_1 + \hat{y}_1)\hat{x}_2 + \hat{x}_1(\hat{z}_2 + \hat{y}_2)] \sin \xi \cos \xi \} \quad (48) \end{aligned}$$

where $\hat{z}_1\hat{z}_2$ is now used to designate $\hat{I}_{z1}\hat{I}_{z2}$, etc., to ease the notation.

During the period $\frac{1}{4}\tau < t < \frac{5}{4}\tau$, the flip angle ξ varies from zero to 180° . In the interval $\frac{1}{4}\tau < t \leq \frac{5}{4}\tau$, the contribution of $\hat{\mathcal{H}}_{zz}$ to $\hat{\mathcal{H}}_{zz}^{(0)}$ can be calculated by assuming the flip angle ξ to be linear in t , so $\xi = \pi(t - \frac{1}{4}\tau)/\tau$, and $dt = \tau d\xi/\pi$. Then, in the period $\frac{1}{4}\tau \leq t < \frac{5}{4}\tau$, or $0 \leq \xi < \pi$, the contribution to $\hat{\mathcal{H}}_{zz}^{(0)}$ is

$$\begin{aligned} \hat{\mathcal{H}}_{zz}^{(0)} &= \frac{1}{t_c} \int \hat{\mathcal{H}}_{zz}(t) dt \\ &= \frac{1}{t_c} \left\{ \tau \hat{I}_1 \cdot \hat{I}_2 - 3[(\hat{z}_1\hat{z}_2 + \hat{y}_1\hat{y}_2 + \hat{z}_1\hat{y}_2 + \hat{y}_1\hat{z}_2)] \right. \\ &\quad \times \frac{\tau}{2\pi} \int_0^\pi \cos^2 \xi d\xi + \hat{x}_1\hat{x}_2 \frac{\tau}{\pi} \int_0^\pi \sin^2 \xi d\xi \\ &\quad \left. + [(\hat{z}_1 + \hat{y}_1)\hat{x}_2 + \hat{x}_1(\hat{z}_2 + \hat{y}_2)] \frac{\tau}{\pi\sqrt{2}} \int_0^\pi \sin \xi \cos \xi d\xi \right\} \\ &= \frac{\tau}{2t_c} [\frac{1}{2}(\hat{\mathcal{H}}_{zz} + \hat{\mathcal{H}}_{yy}) + \hat{\mathcal{H}}_{xx} - \frac{3}{2}(\hat{z}_1\hat{y}_2 + \hat{y}_1\hat{z}_2)] \quad (49) \end{aligned}$$

In the period immediately following $t = \frac{5}{4}\tau$, and before any other pulses are applied,

$$\hat{\mathcal{H}}_{zz} = \frac{1}{2}[\hat{\mathcal{H}}_{zz} + \hat{\mathcal{H}}_{yy} - 3(\hat{y}_1\hat{z}_2 + \hat{z}_1\hat{y}_2)] \quad (50)$$

Proceeding in this manner, it may be verified that the sequence shown in Figure 12, with cycle time $t_c = 6\tau$, yields the following values for the average Hamiltonian associated with the homonuclear dipolar coupling Hamiltonian $\hat{\mathcal{H}}_{zz}$ and the chemical shift $\hat{\mathcal{H}}_{cs} = \sum_{zz} \hat{I}_z$:

$$\begin{aligned} \hat{\mathcal{H}}_{zz} &= -(\hat{I}_{z1}\hat{I}_{y2} + \hat{I}_{y1}\hat{I}_{z2}) \\ &= -(\hat{I}_{z1}\hat{I}_2^+ - \hat{I}_{z1}\hat{I}_2 + \hat{I}_1^+\hat{I}_{z2} - \hat{I}_1^-\hat{I}_{z2})/2i \quad (51) \end{aligned}$$

a pure single quantum operator, and $\hat{\mathcal{H}}_{cs}(0) = 0$.

1 BACKGROUND AND PHENOMENOLOGY

In condensed matter, dipolar interactions among nuclear magnetic moments and their manipulation in multiple quantum (MQ) NMR experiments induce multiple spin correlations. The temporal and spatial development of these collective modes yield information about the structure and the dynamics of spin networks.¹⁻³ In this article, we examine the fundamental aspects of the growth of multiple spin/multiple quantum coherences in extended dipolar coupled spin networks driven by rf magnetic fields.

In MQ NMR, investigations of strongly dipolar coupled spin systems, such as rigid solids, the simplest relevant Hamiltonian needed to describe and understand experimental observations in a laboratory reference frame is given by

$$\hat{\mathcal{H}}(t) = \hat{\mathcal{H}}_Z + \hat{\mathcal{H}}_d + \hat{\mathcal{H}}_{\text{rf}}(t) \quad (1)$$

The contributions to $\hat{\mathcal{H}}(t)$ in equation (1) include the interactions of the nuclear magnetic moments with a strong static magnetic field ($\hat{\mathcal{H}}_Z$), with other nuclear magnetic moments through dipolar interactions ($\hat{\mathcal{H}}_d$), and with time-dependent rf magnetic fields ($\hat{\mathcal{H}}_{\text{rf}}$). Furthermore, $[\hat{\mathcal{H}}_Z, \hat{\mathcal{H}}_d] = 0$, and $[\hat{\mathcal{H}}_Z + \hat{\mathcal{H}}_d, \hat{\mathcal{H}}_{\text{rf}}] \neq 0$.

In order to simplify the description and make connection with experiments, the Hamiltonian of equation (1) is transformed to a frame rotating about the z axis of the laboratory frame at the nuclear spin precession frequency. In this new reference frame, $\hat{\mathcal{H}}_Z$ disappears. A further transformation to

another noninertial frame, the rf toggling frame which ‘follows’ the directions of the rf fields during a pulse sequence, produces an effective Hamiltonian $\hat{\mathcal{H}}_{\text{de}}(t)$. In this newest frame, $\hat{\mathcal{H}}_{\text{de}}(t)$ results from the modulation of $\hat{\mathcal{H}}_d$ by the time-dependent rf fields. The time average of $\hat{\mathcal{H}}_{\text{de}}(t)$ over the period of a cycle of a multiple pulse excitation sequence yields, under appropriate conditions, a time-independent average Hamiltonian $\hat{\mathcal{H}}_d$:

$$\hat{\mathcal{H}}_d = \sum_{j,k} D_{jk} f(\hat{\mathbf{I}}_j, \hat{\mathbf{I}}_k) \quad (2)$$

where D_{jk} is a dipolar coupling constant between spins j and k

$$D_{jk} = \frac{\gamma^2 \hbar^2 (3 \cos^2 \theta_{jk} - 1)}{2r_{jk}^3} \quad (3)$$

and $f(\hat{\mathbf{I}}_j, \hat{\mathbf{I}}_k)$ is a function of bilinear operators involving the components of the spin angular momentum operators $\hat{\mathbf{I}}$, of spins j and k .

Formally, the geometrical interpretations of these transformations correspond to unitary transformations on the state of the spin system (i.e. the density operator) and its dynamical variables (i.e. the spin angular momentum and Hamiltonian operators). The resulting interaction pictures associate different parts of the time dependence of the physical system [i.e. the spins in the sample evolving under the Hamiltonian in equation (1)] to the state of the system and to the dynamical variables. This procedure is generic to all NMR experiments involving the manipulation of spin Hamiltonians. By a judicious choice of a reference frame, different portions of the Hamiltonian can be selected to appear to dominate the spin dynamics; hence, the possibility to discriminate among the various contributions in a spin Hamiltonian. Such an approach underlies the success of NMR spectroscopy. It is noteworthy that these transformations, from one frame to another, inertial or noninertial, do not necessarily preserve the invariance and conservation principles of physics. For example, spin energies measured in the laboratory frame are different from those measured in the rotating frame, while the spin quantum numbers, $I = \frac{1}{2}$ for protons, remain identical. However, observations restricted within a reference frame will be consistent with known laws of physics.

In pulsed NMR experiments, the evolution of the spin system is detected in the rotating frame. The time development of the spin system under $\hat{\mathcal{H}}_d$ in the toggling frame is monitored directly, in multiple pulse line-narrowing sequences such as MREV-8, or indirectly, in MQ NMR, by stroboscopic observations when both the rotating and the toggling frames coincide.

A variety of rf multiple pulse sequences have been tailored to produce different average dipolar Hamiltonians $\hat{\mathcal{H}}_d$. In MQ NMR experiments,¹⁻³ $[\hat{\mathcal{H}}_Z, \hat{\mathcal{H}}_d] \neq 0$. The spin portions [see equation (2)] $f(\hat{\mathbf{I}}_j, \hat{\mathbf{I}}_k)$ of these nonsecular average dipolar Hamiltonians include, among the bilinear spin operators, terms like $\hat{I}_{jz}\hat{I}_{k\pm}$, and $\hat{I}_{j\pm}\hat{I}_{k\pm}$, where $\hat{I}_+$ and $\hat{I}_-$ correspond to the raising and lowering (or ladder) spin angular momentum operators, respectively. These operators in $\hat{\mathcal{H}}_d$ are responsible for the radiative coupling of Zeeman nuclear spin states with differing magnetic quantum numbers M_z by ± 1 and ± 2 .

Evolution under $\bar{H}_d$ for extended periods of time leads to nonstationary states with possibly larger differences in ΔM_z , as discussed in the next section. MQ NMR pulse excitation sequences for solids are specifically designed and optimized to generate multiple spin/multiple quantum coherences among the spins in a macroscopic sample.

The selection rules for the observation of transverse magnetization, or single spin/single quantum coherences, correspond to transitions with $\Delta M_z = \pm 1$. Thus, the creation and evolution of coherent superpositions of quantum states with $\Delta M_z \neq 1$ cannot be detected directly. Indirect piecewise mappings of multiple spin/multiple quantum coherences are accomplished through two-dimensional NMR methods as a function of the excitation and/or evolution times.¹⁻³ MQ NMR spectra obtained in this fashion reveal the presence of multiple spin/multiple quantum coherences with $\Delta M_z = n$, where n is the order of the coherences, in the sample during the excitation/evolution period (see Figure 1).

Figure 1 shows schematic MQ NMR spectra, obtained with time-resolved two-dimensional experiments, as a function of the excitation time. For a fixed excitation period, the spectral intensities decrease with increasing orders. With increasing excitation times, a redistribution of spectral intensities is observed to proceed or to 'flow' towards higher order coherences.

Understanding the behavior of the MQ NMR spectral intensity profiles of solids, as a function of order and excitation time, still poses an interesting challenge to NMR spectroscopists. Specifically, one would like to learn how the multiple spin dynamics depend on the lattice parameters and the space-filling properties of spin networks. Examples of the latter include spatial extent, morphologies, and effective dimensionalities of domain structures on mesoscopic length scales, i.e. in

the range 1 nm to 1 μ m, in condensed matter systems. More generally, the recognition of emergent properties, generic or universal behavior, amidst the complexities of this many-body problem with multiple scales, would deepen our understanding of the fundamental aspects of MQ NMR. These issues are addressed in the following sections, from the perspective of statistical mechanics.

2 ENSEMBLE CONSIDERATIONS

From a macroscopic point of view, in a MQ NMR experiment energy is pumped through rf magnetic fields produced by electronic devices into a solid sample residing in a strong static magnetic field. From a microscopic point of view, this injection of energy proceeds from individual nuclear magnetic moments, embedded in the lattice, to induce multiple spin correlations. Both the microscopic and macroscopic descriptions of the rf irradiation processes involve nonequilibrium driven systems: the macroscopic solid and the microscopic magnetic moments. As these experiments are performed in laboratories on a macroscopic scale, but interpreted microscopically, it is imperative to understand clearly how the macroscopic observables emerge from the numerous microscopic degrees of freedom.

A rigid solid is an aggregate of a large number of spatially fixed atoms. Various solids exist due to the nature of their constituents, which include atoms, ions, or molecules. In MQ NMR of rigid solids, ions and molecules lose their distinct identities on account of the through-space dipolar interactions among all magnetic moments. Hence, the spin network, consisting of the nuclear magnetic moments and their dipolar coupling constants, remains the only relevant and essential substratum onto which the microscopic degrees of freedom, the multiple spin coherences, evolve in MQ NMR experiments.

Solid samples used in MQ NMR investigations typically contain on the order of 10^{20} or more spins. The multiple spin correlations induced in spin networks by present-day MQ NMR methodologies involve coherences with up to possibly 10^2 spins. Consequently, the size difference between the sample and the multiple spin coherences suggests that the macroscopic observables, or responses, in MQ NMR experiments, arise from the random superposition of numerous multiple spin coherences. In other words, the sample could be viewed as an ensemble of loosely coupled subsystems.

Such a description of a macroscopic sample is certainly valid in liquid state NMR experiments, where under normal conditions, molecules behave as essentially independent subsystems. This outlook can also be extended to correlated molecular systems, as observed in critical fluctuations close to critical points.⁴ For example, close to a consolute temperature, the intermolecular interactions among molecules in a critical binary fluid contrive and lead to composition fluctuations over length and timescales that can be quite large compared with those associated with the molecules, but still much smaller than those of the macroscopic sample. However, care must be exercised with such an analogy, since in critical phenomena systems are at equilibrium, while MQ NMR has to do with nonequilibrium driven systems. Possibly a more appropriate comparison for MQ NMR would be with the growth kinetics and processes of domain structures observed during phase

Figure 1 Typical MQ NMR spectra of a rigid solid: spectral intensities $I(n, t)$ as a function of order n and excitation time t , with $t_1 < t_2 < t_3$

Figure 2 A macroscopic sample viewed as an ensemble of loosely coupled N -spin subsystems. Relevant length scales include: the lattice spacing a , the correlation length of a multiple spin coherence ξ , the extent of a subsystem l , and the sample size L , which satisfy $a < \xi < l \ll L$. Spins are denoted by $\bullet$. An 11-spin coherence is also shown, with the lines representing the dipolar coupling constants appearing in the product, which multiplies the corresponding product operator term of the density operator

separation of binary fluids.⁵ In this case, a similarity to critical phenomena exists; however, a richer behavior arises due to the nonequilibrium conditions and nonlinearity. In any event, the point at issue, that a macroscopic sample can be viewed, under certain conditions, as an ensemble of loosely coupled subsystems, where a subsystem can be one or several molecules, or even part of a spin network in a solid, would appear physically plausible.

Figure 2 shows a representation of a macroscopic sample as a statistical ensemble of N -spin subsystems. The number of spins N per subsystem is much smaller, by many orders of magnitude, than the total number of spins in the sample. The relevant length scales in this ensemble include the sample size L , the spatial extent of a subsystem l , the correlation length of the multiple spin coherences ξ , and the underlying lattice spacing a . This hierarchy of length scales satisfy the inequalities, $a < \xi < l \ll L$. Interaction energies between subsystems are assumed to be weak in comparison with interaction energies within the subsystems. This amounts to a neglect of surface effects for the MQ dynamics. Such approximation becomes more accurate in the limit when $\xi \ll l$. These effects are nevertheless necessary to achieve equilibrium or uniform spin temperature in the ensemble. The presence of the long-range dipolar interactions among the magnetic moments would appear to preclude or even invalidate this perspective of the sample as representing an ensemble of loosely coupled subsystems. However, as will be seen in Section 5, in time-resolved MQ NMR experiments, multiple spin coherences are ‘weighted’ by products of dipolar coupling constants. As it turns out, in spin networks, the distributions of dipolar coupling constants and their products are extremely wide. Since, at early excitation times, the MQ spin dynamics are dominated by the largest coupling constants and their products, the ensemble picture remains a good approximation for most experimental conditions. This approximation breaks down for mean field interpretations, e.g. MQ NMR experiments having infinite excitation periods.

Measurements performed over a short period of time on a macroscopic sample, made up of an ensemble of subsystems, correspond to averaging over the ensemble.⁷ When a physical property of a macroscopic system is equal to this property averaged over the subsystems, spatial ergodicity exists. In statistical mechanics, the Gibbs canonical ensemble is composed of identical systems from the macroscopic point

of view, i.e. they all have the same number of particles N , volume V , and temperature T . However, most systems are in different microscopic states. In the ensemble construction for a nonequilibrium driven macroscopic system, as described above, none of the subsystems need to be strictly identical. Instead, one assumes that statistical homogeneity is valid for the subsystems. On a subsystem scale, the statistical properties are stationary in space, i.e. a subsystem is statistically translationally invariant in space. Another feature of time-resolved MQ NMR measurements on such an ensemble, is the fact that, as the multiple spin coherences grow, so does their correlation length ξ . As the inequality $\xi < l$ must be satisfied for a consistent interpretation of the ensemble, this implies that the number of subsystems actually decreases as a function of time. This should be of no significant consequence, as long as $l \ll L$. Under present MQ NMR experimental conditions, these conditions are always satisfied, and the ensembles will consist of huge numbers of subsystems. Such ensembles yield asymptotic statistical states in experimental investigations.

Thus, a time-resolved MQ NMR measurement on a macroscopic solid is assumed to be equivalent to many independent measurements on the subsystems. Since the decomposition of the macroscopic sample into subsystems is not unique, the averaging process over the ensemble implied in a measurement is really a summation over the subsystems. As the spin dynamics are being probed on the scale of a subsystem, the response of the collective ensemble is taken to reflect the behavior of a typical subsystem. Underlying the spin dynamics are dipolar coupling constants and their products. Due to subtleties related to wide distributions and to averaging over products, the role of the couplings is more intricate than appears in the present discussion. For example, the distinction between average and typical behavior is very important in the MQ NMR of large spin networks.⁶ We shall return to these issues in Section 6.

3 QUANTUM MECHANICS OF AN N -SPIN SUBSYSTEM

The focus on the spin dynamics within a subsystem and the subsequent averaging over a large collection of subsystems, yields a more tractable avenue to the understanding of

MQ NMR of solids, rather than treating a single spin system consisting of 10^{20} or more spins. Nevertheless, on the timescale of MQ NMR experiments, the spin dynamics within a subsystem still retain some of complexities of the many-body problem.

In a subsystem consisting of N spins I , there are $(2I + 1)^N$ stationary states of $\hat{\mathcal{H}}_Z$. For $I = \frac{1}{2}$, these 2^N energy levels can be classified according to the magnetic quantum numbers M_z given by

$$M_z = \sum_i^N m_{iz} \quad (4)$$

where m_{iz} is the eigenvalue ($m_z = \pm \frac{1}{2}$) of the i th spin. These Zeeman states, in the magnetic field $\mathbf{B}_0$, have corresponding energies

$$E_z = -\gamma \hbar B_0 M_z \quad (5)$$

and degeneracies

$$\Omega = \frac{N!}{(\frac{1}{2}N + M_z)!(\frac{1}{2}N - M_z)!} \quad (6)$$

The Zeeman manifolds are further broadened by homonuclear dipolar perturbations $\hat{\mathcal{H}}_d$. The resulting energy level diagram can be characterized, in principle, by the combined eigenvalues and eigenfunctions of $\hat{\mathcal{H}}_Z$ and $\hat{\mathcal{H}}_d$. However, due to the presence of bilinear spin operators in $\hat{\mathcal{H}}_d$, the combined eigenfunctions are constructed from direct products of $\hat{\mathcal{H}}_Z$ eigenfunctions. As a consequence, the m_{iz} eigenvalues are not good quantum numbers. In addition, the presence of large N rapidly makes this approach analytically intractable.

Therefore, as a first approximation, only the energy level diagram due to $\hat{\mathcal{H}}_Z$ is considered. This is justifiable, since the Zeeman splittings are usually of the order of tens to hundreds of megahertz as compared with tens of kilohertz for dipolar splittings. Radiative coupling of pairs of Zeeman levels leads to

$$\binom{2^N}{2} = 2^N(2^N - 1)/2 \quad (7)$$

possible transitions. The distinction between $+n$ and $-n$ coherences results in $2^N(2^N - 1)$ transitions. These transitions, or coherences, are classified according to their orders n . The number of coherences of order $n \neq 0$, Z_n , where $|n| \leq N$, is obtained from the constrained sum over the products of degeneracies of coupled Zeeman manifolds,

$$Z_n = \sum_{M_i - M_j = n} \binom{N}{\frac{1}{2}N + M_i} \binom{N}{\frac{1}{2}N + M_j} = \binom{2N}{N - n} \quad (8)$$

The number of coherences within a Zeeman manifold or with $n = 0$, Z_0 , is given by

$$\begin{aligned} Z_0 &= \sum_{M_i = N/2+1}^{-N/2+1} \binom{N}{\frac{1}{2}N + M_i} \left[\binom{N}{\frac{1}{2}N + M_i} - 1 \right] \\ &= \binom{2N}{N} - 2^N \end{aligned} \quad (9)$$

Radiative coupling within a subsystem of N dipolar coupled spins $\frac{1}{2}$ can be rationalized, to a very good degree of approximation, on the basis of the possible $2^N(2^N - 1)$ transitions which connect the 2^N energy levels. The information content needed to describe this physical situation involves $2^N(2^N - 1)$ coherences and 2^N populations, or a total of 4^N parameters.

The 2^N eigenfunctions of $\hat{\mathcal{H}}_Z$, $|r\rangle$, for an N -spin- $\frac{1}{2}$ subsystem, constitute a complete basis set to characterize any spectroscopic experiments involving coherences and populations. As a consequence, any state $|\psi\rangle$ of a subsystem, can be expanded with the complete Zeeman basis set,

$$|\psi\rangle = \sum_{r=1}^{2^N} |r\rangle \langle r|\psi\rangle = \sum_{r=1}^{2^N} c_r |r\rangle \quad (10)$$

$$\langle r|\psi\rangle = c_r \quad (11)$$

Similarly, the observables or expectation values corresponding to any dynamical variables, such as the magnetization M_x , detected in a spectroscopic measurement on a subsystem, can be represented in this basis set with the corresponding operator $\hat{M}_x$ as,

$$\begin{aligned} \langle \psi|\hat{M}_x|\psi\rangle &= \sum_{r,s} \langle \psi|s\rangle \langle s|\hat{M}_x|r\rangle \langle r|\psi\rangle \\ &= \sum_{r,s} c_s^* c_r \langle s|\hat{M}_x|r\rangle \end{aligned} \quad (12)$$

where $c_r = \langle r|\psi\rangle$. The matrix elements $\langle s|\hat{M}_x|r\rangle$ are numbers related to the values of the dynamical variable M_x . The matrix elements, $c_s^* c_r$, are numbers describing the state $|\psi\rangle$ of the subsystem; there are 4^N such matrix elements. As a consequence, this matrix is isomorphic to, or has the same information content as, the description in terms of coherences and populations.^{8,9} The diagonal elements are proportional to the probabilities of occupation of the energy levels, and consequently to the populations. The off-diagonal elements correspond to correlations between the values of the coefficients c_r . For time-dependent problems, as in spectroscopic measurements, these off-diagonal elements are related to coherent superpositions of the stationary states, i.e. coherences or transitions, present in a spin subsystem.

Different states $|\psi\rangle$ yield different values for the same observable, as can be seen from equation (12). The products, $c_s^* c_r$, vary according to the states $|\psi\rangle$, while the matrix elements $\langle s|\hat{M}_x|r\rangle$ remain invariant. It proves convenient to describe the state of the subsystem, with a projection operator for a single state, $\hat{P}_\psi = |\psi\rangle\langle\psi|$, in the Zeeman basis set:

$$\langle r|\hat{P}_\psi|s\rangle = c_s^* c_r \quad (13)$$

With this projection operator, the expectation value of $\hat{M}_x$ in a subsystem becomes [see equation (12)]:

$$\begin{aligned} \langle \hat{M}_x \rangle &= \langle \psi|\hat{M}_x|\psi\rangle = \sum_{r,s} \langle r|\hat{P}_\psi|s\rangle \langle s|\hat{M}_x|r\rangle \\ &= \text{Tr}\{\hat{P}_\psi \hat{M}_x\} \end{aligned} \quad (14)$$

4 QUANTUM STATISTICAL MECHANICS OF AN ENSEMBLE OF N -SPIN SUBSYSTEMS

A measurement of M_x over an ensemble of subsystems is equivalent to averaging over $\langle \hat{M}_x \rangle$ in equation (14). As the state $|\psi\rangle$ or $c_{s,r}^*$ of each subsystem will generally be different, while the dynamical variable will be identical, the averaging gives

$$\overline{\langle \hat{M}_x \rangle} = \sum_{r,s} \overline{\langle r | \hat{P}_\psi | s \rangle \langle s | \hat{M}_x | r \rangle} = \text{Tr}\{\hat{\rho} \hat{M}_x\} \quad (15)$$

with $\hat{\rho}$, the density matrix of the ensemble,^{8,9} defined as

$$\langle r | \hat{\rho} | s \rangle = \sum_{\psi} p_{\psi} \langle r | \hat{P}_{\psi} | s \rangle = \overline{\langle r | \hat{P}_{\psi} | s \rangle} = \overline{c_{s,r}^* c_r} \quad (16)$$

where p_{ψ} is the statistical weight of $|\psi\rangle$ in the ensemble.

For NMR experiments, the density matrix is represented by a density operator, corresponding to the Boltzmann weight of the canonical ensemble with the appropriate Hamiltonian operator defined with respect to some convenient reference frame,

$$\hat{\rho} = Q^{-1} e^{-\hat{\mathcal{H}}/kT} \quad (17)$$

where Q is the ensemble partition function,

$$Q = \sum_{r=1}^{2^N} \langle r | e^{-\hat{\mathcal{H}}/kT} | r \rangle \quad (18)$$

The description of any spectroscopic experiment will involve the time dependence, due to evolution under some Hamiltonian $\hat{\mathcal{H}}$ of $\hat{\rho}$ to characterize the ensemble, or $\hat{P}$ to represent a subsystem. In the Schrödinger picture, the time dependence is assigned to the state of the system, specifically, to the coefficients $c_r(t)$ of equation (11).^{8,9} In MQ NMR experiments of solids, the relevant Hamiltonian corresponds to the time average of $\hat{\mathcal{H}}_d$ in the rf toggling frame, $\hat{\mathcal{H}}_d$ [see equation (2)], over a cycle of the rf excitation sequence. The equation of motion for $\hat{P}$ is obtained by inserting $|\psi\rangle$ into the time-dependent Schrödinger equation to yield^{8,9}

$$\frac{d\hat{P}}{dt} = \frac{i}{\hbar} [\hat{P}, \hat{\mathcal{H}}_d] \quad (19)$$

The averaging of equation (19) over the ensemble of subsystems with identical $\hat{\mathcal{H}}_d$ gives the equation of motion for $\hat{\rho}$:

$$\frac{d\hat{\rho}}{dt} = \frac{i}{\hbar} [\hat{\rho}, \hat{\mathcal{H}}_d] \quad (20)$$

Equation (20) is also known as the Liouville–von Neumann equation.

For a time independent average Hamiltonian, a formal solution to equation (20) is

$$\hat{\rho}(t) = \hat{U} \hat{\rho}(0) \hat{U}^{-1} \quad (21)$$

where the propagator $\hat{U}$ is defined as

$$\hat{U} = \exp\left(-\frac{i}{\hbar} \hat{\mathcal{H}}_d t\right) \quad (22)$$

The interpretation of equation (21) is of importance for understanding the development of multiple spin coherences in time resolved MQ NMR experiments. Insight in this many-body problem, as discussed in the next section, can be gained through a Taylor expansion of $\hat{\rho}(t)$ about $t = 0$:

$$\hat{\rho}(t) = \hat{\rho}(0) + \sum_{n=1}^{\infty} \frac{t^n}{n!} \frac{d^n}{dt^n} \hat{\rho}(t) \Big|_{t=0} \quad (23)$$

From equations (21) and (22), one finds the derivatives of $\hat{\rho}(t)$, of which only the first two are given here:

$$\frac{d\hat{\rho}(t)}{dt} = \frac{i}{\hbar} [\hat{\rho}(0), \hat{\mathcal{H}}_d] \quad (24)$$

$$\frac{d^2 \hat{\rho}(t)}{dt^2} = -\frac{1}{\hbar} [[\hat{\rho}(0), \hat{\mathcal{H}}_d], \hat{\mathcal{H}}_d] \quad (25)$$

Finally, by substituting equations (24) and (25) and all the other derivatives into equation (23), one obtains:

$$\begin{aligned} \hat{\rho}(t) = & \hat{\rho}(0) + \frac{it}{\hbar} [\hat{\rho}(0), \hat{\mathcal{H}}_d] \\ & - \frac{t^2}{2\hbar^2} [[\hat{\rho}(0), \hat{\mathcal{H}}_d], \hat{\mathcal{H}}_d] + \dots \end{aligned} \quad (26)$$

5 DEVELOPMENT OF MULTIPLE SPIN/MULTIPLE QUANTUM COHERENCES IN DIPOLAR COUPLED SOLIDS

The power series in time for $\hat{\rho}(t)$ in equation (26) describes the evolution of the spin dynamics in MQ NMR experiments. With the initial conditions corresponding to the spin system at equilibrium in a strong Zeeman field at a high temperature, equation (17) implies

$$\hat{\rho}(0) \propto \hat{I}_z = \sum_i \hat{I}_{zi} \quad (27)$$

As pointed out in Section 3, since $|\hat{\mathcal{H}}_Z| \gg |\hat{\mathcal{H}}_d|$, it is appropriate to neglect the contributions of $\hat{\mathcal{H}}_d$ in the initial conditions. However, in the toggling reference frame, $\hat{\mathcal{H}}_d$ is crucial for determining the evolution of the spin dynamics. By inserting $\hat{\rho}(0)$ and the nonsecular average Hamiltonian $\hat{\mathcal{H}}_d$ suitable for a particular MQ NMR experiment into equation (26), it is possible to examine the qualitative features of the growth of multiple spin/multiple quantum coherences in a solid.

With $\rho(0)$ corresponding to single-spin interactions and $\hat{\mathcal{H}}_d$ to two-spin interactions, the ascending terms in the expansion of $\hat{\rho}(t)$ describe the sequential growth of multiple spin coherences due to the evolution under $\hat{\mathcal{H}}_d$. In the first-order terms t^1 , the commutators produces two-spin correlations of the form $\hat{I}_{i\alpha} \hat{I}_{j\beta}$, where the components α and β of the spin angular momentum operators are determined by the actual

details of $\hat{\mathcal{H}}_d$. The nested commutators in the second-order terms t^2 yield three-spin operators, $\hat{I}_{i\alpha}\hat{I}_{j\beta}\hat{I}_{k\gamma}$. The hierarchy of nested commutators from the higher order terms t^n generate $(n - 1)$ -spin operators. By introducing ladder (raising and lowering) operators in these product operators, the order n of the corresponding MQCs becomes explicit; the sum of raising operators minus the sum of the lowering operators in a product operator gives the order of the coherence. Thus, to observe an n quantum coherence it is necessary to have, at the minimum, a contribution of order t^{n+1} , implying the presence of an n -spin/ n quantum operator in the expansion of $\hat{\rho}(t)$. Higher order terms can also produce n quantum coherences. The distinction between these different n quantum coherences comes from the number of spins participating in the correlations. Since multiple spin coherences contribute to equation (26) through the product of dipolar coupling constants (as discussed below and in Section 6), the lattice parameters r_{ij} and θ_{ij} will ultimately control and distinguish between the various n quantum coherences.

The interplay between the development of multiple spin coherences and the order of the resulting multiple quantum coherences depends on selection rules associated with the nature of $\hat{\mathcal{H}}_d$ and equation (26). With respect to the time development of the number of spins in multiple spin coherences, the bilinear spin operators of $\hat{\mathcal{H}}_d$ and the algebra of the nested commutators in equation (26) imply a cascade process in the growth of correlations. An n -spin coherence can only grow by sequentially incorporating one single spin at a time, one after another. The time development of multiple quantum coherences is constrained to pathways, in a K -spin/ n quantum space, which depend uniquely on the nature of $\hat{\mathcal{H}}_d$.^{2,10} The pulse excitation sequences for MQ NMR of solids produce generic classes of $\hat{\mathcal{H}}_d$ terms: 2-spin/0,2 quantum operators, 2-spin/1-quantum operators, and 2-spin/2 quantum operators. These excitation sequences achieve a redistribution of MQ NMR spectral intensities according to selections rules on ΔK and Δn . For example, with 2-spin/2 quantum operators in $\hat{\mathcal{H}}_d$, and an $\hat{I}_z$ initial condition, equation (26) and the selection rules $\Delta K = \pm 1$ and $\Delta n = \pm 2$, demonstrate that only even coherences develop; in addition, the evolution cannot generate 4-spin/4 quantum coherences. The redistribution of spectral intensities produced by the different $\hat{\mathcal{H}}_d$ terms is optimized according to the size or spatial distribution of the spins within a subsystem, e.g. for the detection of spin clusters, or extended spin networks.

One of the simplest models, the so-called statistical or Gaussian model,¹ used to interpret MQ NMR spectra of solids, consists of assuming that all the individual coherences possible in an N -spin subsystem have the same magnitudes with random phases, and that all have been excited at long excitation times in the sample or ensemble of subsystems. Time-reversal excitation produces transitions with identical phases within an order.¹¹ Hence, the assumption of a priori equal weight of the different coherences implies that the MQ NMR spectral intensities $I(n,t)$ are proportional to Z_n , [see equation (8)]. Stated differently, the distribution of coherences in the ensemble of subsystems is proportional to Z_n . For large N and small n , it is possible to transform Z_n in equation (8) with Stirling's approximation $y! \approx (2\pi y)^{\frac{1}{2}} y^y e^{-y}$ to give

$$Z_n \approx 4^N (\pi N)^{-\frac{1}{2}} e^{-n^2/N} \quad (28)$$

As a consequence, according to the statistical model, a MQ NMR spectral intensity profile as a function of order $I(n,t)$ should be Gaussian, as suggested by equation (28).

The time dependence of these profiles arises from the growth of the subsystem size $N(t)$. The variance $N(t)$ obtained from fitting $I(n,t)$ to a Gaussian function of n represents the effective number of dynamically coupled spins, in a typical subsystem, following an excitation period of duration t under $\hat{\mathcal{H}}_d$. In addition to spin counting with this variance, it has been suggested that the rate of change in $N(t)$ with time reflects on some of the space-filling properties, such as dimensionality effects, of spin networks.^{1,1,12-14} Qualitatively, three generic classes of behavior have been observed for $N(t)$. Saturation in $N(t)$ implies the presence of isolated clusters of spins. Unbounded growth curves are observed in extended spin networks. Saturation behavior seen at early excitation times, followed by unbounded growth, indicates the occurrence of coupled clusters of spins.

The simplicity of the statistical model accounts for its widespread use in the MQ NMR literature of solids.^{2,3} However, some questions have been raised concerning the validity of the assumption of the a priori equal weight of all coherences.^{2,6} In addition, the convenience of the Gaussian model with the use of simple fitting procedures to analyze MQ NMR spectral intensity profiles is not successful with extended spin networks.¹⁵ To appreciate the nature of these problems, and to understand the development of multiple spin/multiple quantum coherences in solids beyond the level of the statistical model, it is necessary to consider further fundamental aspects of the spin dynamics in MQ NMR.

As discussed in previous sections, the interpretation of MQ NMR experiments of solids relies on the spin dynamics within a subsystem, followed by averaging over an ensemble of subsystems. The density operator $\hat{\rho}$ in equation (17) and its equation of motion [equation (26)] reflect this two-fold averaging: a quantum mechanical averaging or the determination of expectation values in a subsystem [equation (14)], and a statistical averaging over the expectation values due to the distribution of subsystem states in the ensemble [equations (15) and (16)].

It is possible to construct a statistical ensemble of diagrams or graphs, including evolution, which is completely isomorphic with the density operator formalism used to describe MQ NMR.² This approach provides complementary physical insights into MQ NMR spin dynamics, averaging, and measurements. The diagrams include vertices corresponding to spins, and edges or links to delineate dipolar coupling constants between spins. The weight of an edge is proportional to the absolute value of the dipolar coupling constant. The state of a spin is represented by a color. For a spin $\frac{1}{2}$ there are three colors, $\hat{I}_x$, $\hat{I}_y$, and $\hat{I}_z$; generalization to higher spins is possible.

The decomposition of the density operator proceeds by examining an N -spin subsystem, under rigid lattice conditions and without any symmetry elements. In such an N -spin subsystem, the number of distinct subsets n_i each containing i spins is given by the binomial coefficient:

$$n_i = \binom{N}{i} \quad (29)$$

For example, the number of pairs of spins or dipolar coupling constants in a single subsystem is n_2 . The subsets can range in size from $i = 1$ to N . The sum over all possible subsets is:

$$n_T = \sum_{i=1}^N n_i = \sum_{i=1}^N \binom{N}{i} = 2^N - 1 \quad (30)$$

In equation (30), n_T is the sum of all possible spin correlations in the spin subsystem. By including the states of the spins or colors within the spin correlations, one obtains

$$n_T^c = \sum_{i=1}^N n_i 3^i = \sum_{i=1}^N \binom{N}{i} 3^i = 4^N - 1 \quad (31)$$

where n_T^c is the total number of distinct colored subsets, and is equal to the number of elements (coherences and populations) of the normalized density operator in an N -spin- $\frac{1}{2}$ subsystem.

The growth of multiple spin/multiple quantum coherences is described by equation (26). From the interpretation of this equation, the coherences were seen to grow sequentially by adding one spin after another with increasing time. It is clear that this description is valid for the density operator, either in the product operator formalism or in the ensemble of colored spin correlations described above.

However, there is an essential feature related to the growth processes and the averaging over the subsystems, which becomes more obvious with the diagrams. Consider a generic term of $(n + 1)$ th order in the Taylor expansion of equation (19) for the time dependence of the projection operator $\hat{P}_\psi$. The resulting equation is analogous to equation (26) with $\hat{P}_\psi$ replacing $\hat{\rho}$. The product of spin operators will include n -spin operators corresponding to different spins in the subsystem. As $\hat{\mathcal{H}}_d$ is present in the nested commutators, there will also be products of $(n - 1)$ dipolar coupling constants which multiply the n -spin product operators. For example, a 3-spin coherence involving spins i, j , and k , will have a corresponding product operator of the form $\hat{I}_{i\alpha}\hat{I}_{j\beta}\hat{I}_{k\gamma}$, multiplied by a product of dipolar coupling constants $D_{ij}D_{jk}$. Hence, in general, the contributions or weights of n -spin coherences in the equation of motion are determined by products of $(n - 1)$ dipolar coupling constants. A diagram, consisting of n vertices connected with $(n - 1)$ edges is called a tree; no loops are permitted in such a graph. The number of ways to connect n vertices, with $(n - 1)$ edges chosen among $\binom{n}{2}$ distinct edges, corresponds to the number of distinct trees given by

$$n^{n-2} \quad (32)$$

Equation (32) also gives the number of products of n dipolar coupling constants for a particular n -spin coherence. In an N -spin subsystem, the total number of products of n dipolar coupling constants for n -spin coherences is

$$\binom{N}{n} n^{n-2} \quad (33)$$

The averaging over an ensemble of subsystems, in order to obtain $\hat{\rho}$, as discussed in Section 4 and in NMR texts,^{8,9} proceeds by assuming that the Hamiltonians are identical for all

subsystems [see equations (19) and (20)]. This is certainly true for a hypothetical representative ensemble, or approximately true for a sample viewed as an ensemble of loosely coupled subsystems, as presented in Section 2. However, when the averaging is done over a nonequilibrium ensemble for a finite sample, care must be taken to distinguish between the sum in the Hamiltonian [see equations (2), (19) and (20)] and the realizations of multiple spin correlations (with corresponding product operators) present in the ensemble. As an example, consider a 25-spin subsystem. In this subsystem, there is only a single MQ coherence of order 25 represented by a product operator consisting of 25 raising operators. According to equation (26), the 25-spin/25 quantum coherence is weighted by a product of 24 dipolar coupling constants. Among these spins, there are $\binom{25}{2} = 300$ distinct dipolar coupling constants. The number of distinct products of 24 dipolar coupling constants corresponds to the number of trees, in this case $25^{23} \approx 10^{32}$ realizations. It should be clear that a macroscopic sample consisting of 10^{20} spins will not have enough 25-spin subsystems to represent all trees or possible realizations of the 25-MQ coherence. An MQ NMR measurement on a macroscopic sample, consisting of an ensemble of subsystems, is really an average over the subsystems [see equation (16)]. The average over multiple spin coherences is really performed over the distribution of corresponding trees present in the ensemble, i.e. over products of dipolar coupling constants. To appreciate the intricacies of such a measurement or averaging procedure, we now examine the distributions of dipolar coupling constants and their products in spin networks.

6 STATISTICAL PROPERTIES OF DISTRIBUTIONS OF DIPOLAR COUPLING CONSTANTS AND THEIR PRODUCTS IN LARGE SPIN NETWORKS

Consideration of equation (26) demonstrated that different multiple spin coherences contribute to the evolution of ρ according to the values of the products of dipolar coupling constants. Thus, for a finite excitation time, coherences cannot be treated equally, as is assumed in the Gaussian statistical model.¹ Only in the limit of an infinite excitation time will all the coherences contribute equally to the spin dynamics.⁶ The recognition that in spin networks the distributions of dipolar coupling constants and their products are characterized by asymmetry associated with extreme widths is important for understanding MQ NMR spin dynamics.⁶ Difficulties encountered with the interpretation of equation (26), due to the presence of multiple length- and timescales, actually arise from these broad and peculiar distributions.

In three-dimensional solids, lattice sums of dipolar coupling constants can be replaced by a continuum approximation involving integrals such as

$$\sum_{i,j} D_{ij} \propto \int_r (1/r^3) r^2 dr \propto \ln r \quad (34)$$

For an infinite sample, the lattice sum diverges, while for finite spin networks the sum is conditionally convergent, i.e. it depends on the sample shape. Some approaches, such as the Ewald summation and the Lorentz cavity method, have

been devised to study these distributions in samples of general shapes.

In one-dimensional solids, the lattice sums can be performed analytically. Consider an infinite crystalline one-dimensional chain of spins with lattice parameter r oriented perpendicular to the Zeeman field. The average dipolar coupling constant per spin $\langle D \rangle_s$ is

$$\langle D \rangle_s = 2 \sum_{k=1}^{\infty} \frac{1}{2} \gamma^2 \hbar^2 (kr)^{-3} \approx 1.20 \gamma^2 \hbar^2 / r^3 \quad (35)$$

In this case, 83% of the average is determined by the value of two nearest neighbor couplings out of an infinity of couplings!

Figure 3 shows a schematic distribution of the absolute values of dipolar coupling constants and their logarithms for a large spin subsystem. One should note that the distribution in Figure 3(a) is really a caricature, since in large networks the width essentially cannot be observed on linear scales.⁶ Several statistical features are illustrated by Figure 3. The average $\langle |D| \rangle$ is determined by the coupling constants in the tail of the distribution, while the most probable value $|D|_{MPV}$ is sensitive to the small and numerous long-range couplings. The transformation of the distribution on a logarithmic scale demonstrates the huge dynamic range of the distribution. For example in a two-dimensional square lattice of $10^2 \times 10^2$ spins, the distribution of coupling constants covers over 10 orders of magnitude. Differences between $\langle \ln |D| \rangle$ and $\ln \langle |D| \rangle$ are important to reconcile with measurements on an ensemble. The value of $\langle |D| \rangle$ is sensitive to the largest coupling constants, while $\langle \ln |D| \rangle$ is more sensitive to the details of the overall distribution. Such distinctions are significant in the physics of

Figure 3 (a) Schematic distribution of the absolute values of dipolar coupling constants in an N -spin subsystem. (b) Schematic distribution of the logarithm of the absolute values of dipolar coupling constants in the same subsystem. Note the difference between $\langle \ln |D_{ij}| \rangle$ and $\ln \langle |D_{ij}| \rangle$. The analogous distributions, involving products of dipolar coupling constants, show similar behavior, but with wider distributions

disordered systems.^{16,17} Products of dipolar coupling constants show similar features; however, the distributions are even wider.⁶

Probably the most interesting feature of these distributions arises from the scaling behavior of the statistical properties as a function of N , the number of spins. The relative fluctuations RF,

$$RF = \frac{(\langle |D|^2 \rangle - \langle |D| \rangle^2)^{\frac{1}{2}}}{\langle |D| \rangle} \quad (36)$$

measure the relative spread about the mean. In the limit of large spin networks,

$$RF \propto N^{-\frac{1}{2}} \quad (37)$$

This result implies that the distributions become wider as N increases, i.e. there is no self-averaging. The ratio of the most probable value to the first moment can be shown to scale as $N^{+\frac{3}{2}}$. The product of dipolar coupling constants shows a similar behavior with the same scaling exponents.⁶ Such behavior is highly counterintuitive, since in random additive processes, within the central limit theorem, the relative fluctuations scale as $N^{-\frac{1}{2}}$, and the most probable value coincides with the first moment in the thermodynamic limit.

Some implications of these results for the growth of multiple spin coherences/multiple quantum coherences are beginning to emerge.^{2,18} For example, anisotropy effects in the growth process should be determined by the products of the angular contributions of dipolar coupling constants. In a measurement on an ensemble of subsystems, the realizations of multiple spin coherences which are detected should be those with the largest products of dipolar coupling constants. However, these products are the least numerous but still dominate the dynamics due to their large weights. This last result would suggest that a single subsystem, where a multiple spin coherence with the largest possible product has been excited, could eventually dominate a macroscopic measurement. The statistical properties of the distributions of dipolar coupling constants and their products should also be relevant for other aspects of strongly dipolar coupled spin systems; examples include problems associated with FIDs¹⁹ and the lineshapes,²⁰ spin diffusion,²¹ and spin temperature.²²

7 DYNAMICAL SCALE INVARIANCE IN THE GROWTH OF MULTIPLE SPIN CORRELATIONS IN DIPOLAR COUPLED SOLIDS

Dilation or scaling symmetry, observed under certain conditions in some physical systems, is a generalization of the concept of similarity among geometrical objects. In geometry, the properties of two circles with different radii are similar to one another by simple transformations of scales. In physical sciences, the practical aspects of scaling involve the determination of the relevant scaled variables to describe a phenomenon, such that all data acquired under a range of conditions collapse onto some single universal plot. Thus, scaling reveals an invariance or a kind of unification among the relevant scaled variables, which was not obvious

in the original unscaled variables. Understanding the physical reasons underlying scaling symmetry usually leads to deeper insights into the phenomenon.

Some scaling arguments have been applied to various aspects of the growth of multiple spin/multiple quantum coherences in solids.^{1,2,15,23} In the context of the Gaussian statistical model, studies have focused on the behavior of the variance $N(t)$ in dilution effects¹ and power law growth² in spin networks, and dimensional analysis of growth curves.²³ A more elaborate scaling analysis of MQ NMR spectral intensity profiles, as a function of order and excitation time, demonstrated non-Gaussian behavior in extended spin networks.¹⁵ These studies also provided additional support for the case of exponentially decaying intensity profiles. Behind these approaches lies the belief that the physics of the growth processes should be invariant or scale free, for some range of length- and timescales.

Baum et al.¹ have studied the effects of dilution of spin networks with MQ NMR. With increasing dilution, the growth curves $N(t)$ were shifted to longer excitation times. When the excitation time was multiplied by a scaling factor, all growth curves for the diluted systems could be collapsed onto the data of the undiluted or 'pure' spin network. In this case, the scaling symmetry demonstrates the invariance of the physics of the growth processes in the pure and diluted spin networks. A simple dilution in time relates these different systems. The scaling factor was observed to be a function of dilution; no serious attempts were made to understand this phenomenology.

Lacelle² has studied the growth curves $N(t)$ of a large variety of solid samples. All the data were seen to follow power law behavior,

$$N(t) \propto t^\alpha \quad (38)$$

where α is a growth exponent characteristic of the samples and the growth mechanism. The presence of power law growth indicates a scale invariant process, such that the functional

$$N(\lambda t) = \lambda^\alpha N(t) \quad (39)$$

exists for any values of the scaling factor λ . The solution of equation (39), i.e. equation (38), is obtained by setting $\lambda = 1/t$ in equation (39). In order to determine the physics behind the growth exponents, several models were considered. For example, in diffusive growth, the length scale ξ of the multiple spin correlations should follow

$$\xi \propto t^{1/2} \quad (40)$$

The space-filling properties of a homogeneously embedded solid in D dimensions imply that

$$N \propto \xi^D \quad (41)$$

Equations (40) and (41) yield

$$N \propto t^{D/2} \quad (42)$$

from which the growth exponent $\alpha = D/2$ is deduced for a diffusive growth mechanism. None of the models developed could account successfully for all the observed growth

exponents. However, a classification of the spin networks could be achieved with the long time behavior of the growth rates

$$\frac{dN}{dt} \propto t^{\alpha-1} \quad (43)$$

When $\alpha < 1$, the growth rates converge to zero at long excitation times, implying the presence of clusters of spins. When $\alpha > 1$, a divergence in the growth rates should occur, which indicates the presence of an extended network. The case of $\alpha = 1$ corresponds to the threshold between these regimes. In a sense, α serves as a localization/delocalization criterion for multiple spin coherences.

Scruggs and Gleason²³ have examined the growth curves of different simple crystalline materials. By assuming that the growth processes were only determined by a relevant time-independent scale, the inverse of the square root of the second moment of the dipolar linewidths, the different growth curves collapsed onto a single universal curve for early excitation times. Their assumption for this empirical scaling is implicitly equivalent to assuming that the growth processes are dominated by nearest neighbor couplings, since Van Vleck's second moment is also dominated by such couplings.

One could argue about the quality and the quantitative aspects of the fitting procedures with the Gaussian approximation in these studies.^{1,2,23} However, the value of such studies really lies in the efforts made to explore the possible facets of scaling in the growth processes of multiple spin/multiple quantum coherences. To ascertain any quantitative aspects of scaling, for example, growth exponents, under these circumstances it is clear that many more experiments involving high quality data will be required.

Lacelle et al.¹⁵ have developed some scaling arguments in order to test the validity of the Gaussian statistical model. In particular, they strived to observe the scaling of MQ NMR spectra, as a function of order and excitation times, in extended spin networks. The Gaussian dependence suggested for the spectral intensity profiles $I(n,t)$ in equation (28) is actually a generalized homogeneous equation. With the time dependence of the variance $N(t)$ corresponding to a random walk model in product operator space,^{1,10} the expected scaling, $I(n,t)/t^{-1/2}$ versus $n/t^{1/2}$, should have collapsed all MQ NMR spectra for a sample onto a single universal spectrum. The lack of scaling clearly demonstrated non-Gaussian behavior. Instead, consideration of the multiplicative nature of the coupling constants associated with product operators in equation (26) led to a heuristic argument predicting exponential decaying intensity profiles. The ensuing scaling analysis collapsed MQ NMR spectra, obtained at different excitation times, onto a single universal spectrum, thereby demonstrating dynamical scale invariance in the growth process of multiple spin/multiple quantum coherences. Such an approach reveals some aspects of the complexities, richness, and subtleness of multiple spin dynamics in MQ NMR of solids.

1 INTRODUCTION

Multiple quantum (MQ) NMR can provide unique insight into the distribution and motion of nuclei in solids. In this article, we consider multiple quantum coherences associated with homonuclear dipolar coupling among spin- $\frac{1}{2}$ nuclei in solids. Therefore, we consider nuclei with high natural isotopic abundance and a high gyromagnetic ratio. ^1H MQ NMR has been applied to study organic solids,^{1–3} amorphous semiconductors,^{4–7} and adsorbates on catalysts^{8–14} and chromatography columns.¹⁵ In addition, ^{19}F MQ NMR has been used to study bulk salts,¹⁶ photosensitive salt/polymer mixtures,^{17–19} and bulk polymers.²⁰ MQ NMR of ^{31}P in solids has also been demonstrated.²¹ Several review articles and textbook chapters on MQ NMR experiments and their applications are available.^{21–29}

The rate of MQ coherence development depends on the strength and time dependence of each pairwise homonuclear dipolar coupling as well as the number of such pairs. For a network of N equivalent nuclei, the second moment M_2 of the distribution of all the pairwise homonuclear dipole couplings can be related to the geometry of the spin distribution through the van Vleck equation:³⁰

$$M_2 = \frac{3}{4} \gamma^4 \hbar^2 \frac{I(I+1)}{2} \sum_{i < j}^{N-1} \frac{(1 - 3 \cos^2 \theta_{ij})^2}{r_{ij}^6} \quad (1)$$

Thus, many combinations of internuclear distances r_{ij} and the total number of pairs in the summation $N - 1$ can give rise to identical M_2 . Using MQ NMR, the number and distribution of dipolar couplings can be investigated independently, thus allowing the distribution of nuclei in a solid to be explored.

Observation of MQ coherence development in solids is accomplished interferometrically via a two-dimensional NMR technique.^{1,29} By incrementing the MQ preparation time τ , the presence of finite clusters of nuclei can be distinguished from nuclear distributions which are homogeneous on the 1–2 nm length scale of this experiment.^{2,3} Coherences arising from a

cluster of nuclei will saturate with increasing MQ excitation time, because no additional nuclei are available for correlation in the surrounding region. In contrast, the number of nuclei coupled together in a large homogeneous dipole network will increase monotonically with time until relaxation occurs.

Furthermore, a simple scaling exists for the growth of MQ coherences among many bulk materials.^{16,31} This behavior allows homogeneous three-dimensional distributions of nuclei to be differentiated from one- and two-dimensional distributions.^{31–33} Identification of two-dimensional distributions is particularly valuable for determining whether a given nuclear species, such as ^1H , ^{19}F , or ^{31}P , is segregated at a surface,^{31,34} such as a grain boundary in a polycrystalline material. A model which expands the density matrices in terms of average product operators allows these differences to be evaluated numerically.³¹

More complex distributions of nuclei can also be analyzed using MQ NMR. For example, both isolated salt molecules and large aggregates of salt have been observed simultaneously within polymeric matrices.^{17–19} Finally, MQ NMR and its relaxation may serve as a valuable probe of molecular reorientation in solids which modulate the dipolar coupling network at frequencies in the kilohertz range.^{20,35,36}

2 MQ COHERENCE INTENSITIES

Analysis of MQ intensities is the underlying principle for using MQ NMR as a ‘spin-counting’ technique, allowing the number of dipole coupled nuclei in a isolated cluster to be determined.³ Although only two possible states, α and β , exist for an individual spin- $\frac{1}{2}$ nucleus, when N of these nuclei are dipole coupled there are 2^N possible product states. Thus, a $2^N \times 2^N$ density matrix is required to represent fully the time development of MQ coherence intensity among N dipolar coupled spin- $\frac{1}{2}$ nuclei. A schematic representation of ρ for $N = 3$ is shown in Figure 1, where the indices of the matrix are the eight possible product states. Diagonal elements can be used to calculate the populations of the product states, while the off-diagonal elements indicate the MQ coherences between two different states.

The MQ coherence order, n , is equal to the difference in m_z between the two states. Since the z component of angular momentum m_z of an individual spin state is $\pm\frac{1}{2}$, m_z for the product states ranges from $-N/2$ to $+N/2$. Thus, MQ orders can be positive, negative, or zero, provided that $|n| \leq N$. This limitation provides a very elegant way of determining the number of dipole coupled spins in a spatially isolated cluster. However, there is only one way to achieve such an $n = N$ coherence, making it statistically difficult to observe intensity in highest MQ order for large N . Fortunately, the number of density matrix elements Z_n for lower order coherences ($|n| < N$) also depends on the number of coupled nuclei:

$$Z_n = \sum_{i < j} \delta_{[(m_{zi} - m_{zj}), n]} = \binom{2N}{N - |n|} \quad (2)$$

In this equation, Z_0 includes both off-diagonal elements with $n = 0$, representing true zero quantum coherence (0Q), and diagonal elements representing self-correlation among the

Figure 1 Schematic representation of ρ for $N = 3$. The 2^3 product states are sorted by m_z so that elements corresponding to even MQ coherences ($n = 0$, black; $|n| = 2$, striped) appear in the upper left and lower right quadrants. The remaining elements correspond to odd MQ orders ($|n| = 1$, white; $|n| = 3$, grey)

states, as no difference is resolved between these two types of element by most MQ experiments.

Each element in Figure 1 is shaded according to the absolute value of its corresponding MQ order. Note that the first $4^{N/2}$ indices in Figure 1 represent the states with $m_z = (N - k)$, where k is an integer. Thus, elements corresponding to even order MQ coherences will appear only in the upper left and lower right quadrants of the density matrix. The remainder of the elements in the upper right and lower left quadrants correspond to odd order MQ coherences. If only even order MQ coherences are excited, this density matrix will be block diagonal with only $4^{N/2} = 32$ possible nonzero elements. For $N = 3$, the number of elements contributing to the even orders will be $Z_0 = 20$ and $(Z_2 + Z_{-2}) = 12$.

At equilibrium, the density matrix is proportional to I_z . Thus, only the diagonal elements are nonzero. As MQ excitation begins, intensity develops in density matrix elements of low MQ order. Longer excitation times are required for growth of high-order MQ coherences. The n quantum intensity at any time τ after MQ excitation is begun $I_n(\tau)$, contains contributions from all Z_n density matrix elements comprising that order:³⁷

$$I_n(\tau) = \sum_{i < j} \delta_{[(m_{zi} - m_{zj}), n]} |\rho_{ij}(\tau)|^2 \quad (3)$$

Thus, calculation of MQ dynamics requires following the time evolution of the density matrix under the influence of the Hamiltonian corresponding to the MQ excitation sequence during the experiment.

The Liouville von Neumann equation of motion can be used to calculate $\hat{\rho}(\tau)$ explicitly:

$$\frac{d\hat{\rho}(\tau)}{d\tau} = i[\hat{\rho}(\tau), \hat{\mathcal{H}}] \quad (4)$$

where $\hat{\mathcal{H}}$ is the Hamiltonian applied to the system for a duration τ in order to develop MQ coherences. If average

Hamiltonian theory can be applied, the solution of equation (4) is

$$\hat{\rho}(\tau) = \exp(-i\hat{\mathcal{H}}\tau)\rho(0)\exp(i\hat{\mathcal{H}}\tau) \quad (5)$$

For small numbers of spins ($N \leq 9$), the development of $I_n(\tau)$ has been calculated explicitly using equations (3) and (5).^{32, 37, 38}

However, tracking the time development of the 4^N density matrix elements is a large task for any significant number of coupled spins. For $N = 95$, the number of density matrix elements exceeds the number of hydrogen atoms in the Earth's sun! Thus for a large N , statistical limit behavior is often assumed, in which all MQ coherences have equal probability, allowing the magnitude of all density matrix elements to become equal at long excitation times.

The assumption of a statistical limit³⁷ greatly simplifies the analysis of MQ coherence intensities since the intensity of an n quantum coherence depends only on the number of elements of that order Z_n :

$$I_n = \frac{C Z_n}{4^N} \quad (6a)$$

The inverse of the constant C represents the fraction of density matrix elements where nonzero intensity could be excited. This fraction depends upon the selectivity of the Hamiltonian applied to the system. When nonselective excitation is used, all MQ orders are excited and $C = 1$. However, selective MQ excitation is often used. For instance, if only even MQ orders are excited, $C = 2$. Since equation (2) shows that Z_n is a function of n and N only, the distribution of $I_n(\tau)$ allows N to be determined. When $N \geq 6$, the right-hand side of equation (6a) can be approximated by a Gaussian distribution:

$$I_n \simeq \frac{C}{\sqrt{N\pi}} \exp(-n^2/N) \quad (6b)$$

Equations (6a) and (6b) are valid for all positive, negative and zero integer values of n , and are normalized such that

$$\sum_{n=-\infty}^{\infty} I_n = 1 \quad (7)$$

In addition, note that the MQ intensity distribution is symmetric, $I_n = I_{-n}$, and that I_0 contains both populations and true 0Q coherences. Furthermore, higher order coherences are statistically more difficult to achieve than lower order coherences. As will be shown below, I_0 tends to deviate more from the predicted values than the positive orders; only the latter are generally utilized to determine N . Statistical limit behavior is often a poor assumption for very small groups of spins, due to presence of symmetry forbidden transitions.

3 MQ EXCITATION BY $\hat{\mathcal{H}}_{yx}$

One of the most desirable Hamiltonians for exciting MQ coherences in solids is $\hat{\mathcal{H}}_{yx}$:

$$\hat{\mathcal{H}}_{yx} = -\frac{1}{2} \sum_{i < j} R_{ij} (\hat{I}_{i+} \hat{I}_{j+} + \hat{I}_{i-} \hat{I}_{j-}) \quad (8)$$

Other Hamiltonians such as $\hat{\mathcal{H}}_{zx}$ have been used for exciting MQ coherences. However, higher orders develop more quickly under $\hat{\mathcal{H}}_{yx}$,³⁸ maximizing the number of spins that can be correlated before relaxation effects become significant.

The bilinear raising and lowering operators $\hat{I}_{+i}\hat{I}_{+j}$, and $\hat{I}_{-i}\hat{I}_{-j}$ allow only even-order MQ coherence intensity to evolve when $\hat{\mathcal{H}}_{yx}$ is utilized in conjunction with an equilibrium initial density matrix $\rho(0)$ that is proportional to $\hat{I}_z$. When only half of all possible orders are excited, the intensity of each is twice that of a nonselective experiment [equation (6)]. The increased intensity is particularly important for detecting high-order coherences, which are statistically less likely than lower order coherences. Odd order and nonselective excitation using $\hat{\mathcal{H}}_{yx}$ results when prepulses create an initial density matrix proportional to the single quantum operator $\hat{I}_x$ or it can be made nonselective if $\rho(0)$ is a mixture of $\hat{I}_z$ and $\hat{I}_x$, respectively.⁴⁰

For spin counting applications it is important to note that the selection rules for $\hat{\mathcal{H}}_{yx}$ from an initial density matrix proportional to $\hat{I}_z$ result in the inability to create $n = N$ quantum coherence. Obviously, N quantum coherence cannot be developed when N is odd. More surprisingly, N quantum coherence cannot be achieved among $N = 4k$ dipole coupled spins, where k is a positive integer.⁴⁰ Thus, four quantum coherence cannot develop among an isolated cluster of four coupled nuclei. While these limitations appear problematic, the ability to achieve N quantum coherence via other MQ propagators can be even more restrictive. For instance, under $\hat{\mathcal{H}}_{zx}$ the N quantum order can never be achieved when starting from the equilibrium density matrix. The restrictions on creating N quantum coherence are only significant for size determination among very small clusters of nuclei. In larger dipole coupled networks, the signal-to-noise ratio of the highest order MQ coherence is generally below the detection limit, rendering the ability to achieve this coherence insignificant.

To carry out the MQ experiment in the laboratory, the phase ϕ of $\hat{\mathcal{H}}_{yx}$ is generally varied.^{1,2} One or more repetitions of the eight-pulse cycle shown below have been used to create $\hat{\mathcal{H}}_{yx}(\phi)$:

$$\begin{aligned} &(\Delta/2) - 90^\circ_\phi - (\Delta') - 90^\circ_\phi - (\Delta) - 90^\circ_\phi - (\Delta') - 90^\circ_\phi - \\ &(\Delta) - 90^\circ_{\phi+180^\circ} - (\Delta') - 90^\circ_{\phi+180^\circ} - (\Delta) - 90^\circ_{\phi+180^\circ} - \\ &(\Delta') - 90^\circ_{\phi+180^\circ} - (\Delta/2) \end{aligned}$$

where $\phi = 0^\circ$ corresponds to an x pulse. The relationships between the delays is $\Delta' = 2\Delta + t_p$, where t_p is the pulse length. The average Hamiltonian, $\hat{\mathcal{H}}_{yx}(\phi)$ is then

$$\begin{aligned} \hat{\mathcal{H}}_{yx}(\phi) = & -\frac{1}{2} \sum_{i < j} R_{ij} [\hat{I}_{i+}\hat{I}_{j+} \exp(2i\phi) \\ & + \hat{I}_{i-}\hat{I}_{j-} \exp(-2i\phi)] \end{aligned} \quad (9)$$

Considering $0^\circ \leq \phi < 360^\circ$, $\hat{\mathcal{H}}_{yx}(\phi) = \hat{\mathcal{H}}_{yx}$ at $\phi = 0^\circ$ or 180° and $\hat{\mathcal{H}}_{yx}(\phi) = -\hat{\mathcal{H}}_{yx}$ at $\phi = 90^\circ$ or 270° . During the

mixing period, the value of ϕ is fixed at 90° , corresponding to $-\hat{\mathcal{H}}_{yx}$.

In the presence of heteronuclear couplings, the $\hat{\mathcal{H}}_{yx}$ sequence can be used to examine the distribution of I spins without irradiation of the S spin frequency or reduction of the I - S couplings by isotopic exchange.¹⁶ This is particularly important when both ^{19}F and ^1H are present in the sample of interest.

As in any multiple pulse NMR experiment, deviations from perfect delta pulses, finite pulse cycle times with respect to the inverse frequencies of the interactions in the sample, and off-resonance effects can lead to undesirable effects.⁴² The sensitivity to chemical shift offset has recently been exploited to measure the correlation length of the chemical shift shielding tensor in polycrystalline solids.⁴³ This increased sensitivity of higher order coherences to magnetic field gradients has also been exploited to enhance the spatial resolution of NMR imaging of solids.⁴⁴ In the future, excitation using shaped rf pulses has the potential for improving experimental implementation of the MQ experiment.⁴⁵ In practice, rectangular pulses with $t_p \leq 3 \mu\text{s}$ and eight-pulse cycle times t_c , of 30 – $72 \mu\text{s}$ are generally employed, and the experiment is carried out on resonance.

4 MEASURING MQ INTENSITIES

Although MQ coherences have sometimes been detected directly by CW NMR,²² MQ coherences cannot be detected directly by FT NMR. Since MQ intensities are nonlinear under CW experiments, two-dimensional NMR experiments are currently employed for this purpose. Only an overview of the required experimental procedure is provided below. Additional descriptions can be found in Yen and Pines,¹ Baum et al.,² Baum and Pines,³ and Gleason.²¹

As in most two-dimensional NMR experiments, there are four distinct periods: preparation, evolution, mixing, and detection. During the preparation period, of length τ and phase ϕ , MQ coherences are excited as a result of homonuclear dipole couplings, and nonzero intensity is developed in the off-diagonal elements of the density matrix [equation (9)]. However, no observable magnetization from these elements can be detected experimentally. These coherences evolve during t_1 , the evolution period time. The mixing period of length τ (identical to the preparation period length) and phase $\phi = 90^\circ$, converts MQ coherences in the off-diagonal elements back into diagonal elements, corresponding to z magnetization. Finally, the detection period is used to create observable signal $S(\phi, \tau)$.

In order to resolve the various n quantum coherences, the phase of the preparation period ϕ is changed from 0 to 360° in increments of $\Delta\phi$, while the preparation period length, the mixing period length, and the phase of mixing period are held fixed. Fourier transformation of this series of $S(\phi, \tau)$ at constant τ with respect to ϕ yields the intensities of the n quantum orders $I_n(\tau)$. At least $2n$ phase shifts must be performed when detectable n quantum intensity is present. Fewer phase shifts will alias high-order coherence intensity to lower values of n . Most commonly, $\Delta\phi$ is set at 5.6° or 2.8° , allowing detection of $|n| \leq 16$ and 32 , respectively.

In order to determine the local distribution of nuclei within a sample, $I_n(\tau)$ is measured for a series of τ . Generally,

$\tau = n_c t_c$ which corresponds to changing the integer number of repetitions n_c , of the basis eight-pulse MQ subcycle for $\hat{\mathcal{H}}_{yx}$. In a given sample, longer τ values correspond to probing the dipolar network over increasing distances.

The length of the evolution period t_1 can also be incremented, allowing MQ coherences to evolve under the internal Hamiltonian of the spin system, yielding the n quantum coherence lineshapes.¹ However, for many applications, only the integrated intensity of the coherence is required. Thus, the evolution period time t_1 is often set to zero,^{5,46} maximizing the final signal intensity and significantly decreasing acquisition time. This also eliminates the effects of couplings linear in $\hat{I}_z$ such as chemical shift and heteronuclear dipole coupling during the evolution period.

When $t_1 = 0$ and relaxation effects are neglected, the density matrices at times 0 and 2τ are identical when $\phi = 0^\circ$ or 180° , so called ‘time reversal’. At other ϕ some transverse magnetization will also be present at the end of the mixing period and the magnitude of z magnetization will be reduced. Thus, prior to the detection period, a delay which is long compared to T_2 but short compared to T_1 allows for decay of any transverse magnetization transients. Then, a $\pi/2$ pulse can be applied to detect $S(\phi, \tau)$. Spin locking with periodic sampling can be employed during the detection period to enhance the signal-to-noise ratio of $S(\phi, \tau)$.

5 SMALL DIPOLE COUPLED NETWORKS

Even when the number of dipole coupled spins is small, the dynamics of MQ coherence growth can become quite complicated. The simplest possible system to consider is isolated pairs ($N = 2$) of spin- $\frac{1}{2}$ nuclei with identical internuclear separations and orientations with respect to the external magnetic field. Thus, all intrapair dipole coupling constants R are identical and much stronger than any interpair coupling. Then, even order selective excitation by $\hat{\mathcal{H}}_{yx}$ allows only the zero quantum and ± 2 quantum intensity to develop as given by the analytical solution to equation (5):

$$I_2(\tau) = I_{-2}(\tau) = \frac{1}{2}[1 - I_0(\tau)] = \frac{1}{2}[1 - \cos(R\tau)] \quad (10)$$

In the absence of relaxation, the oscillatory exchange of MQ coherence intensity between the orders will continue indefinitely.³⁸

In a macroscopic NMR sample, such as a single crystal or a liquid crystal, identical orientations of internuclear vectors with respect to the external magnetic field can occur. By contrast, polycrystalline powders are the most commonly used samples for MQ NMR. Even for isolated pairs with identical internuclear spacings, the angular dependence of the dipolar coupling interaction leads to destructive interference among the characteristic frequencies which contribute to the MQ intensity development, leading to steady state values of I_n at long τ .

The appearance of oscillations which are damped at long times is characteristic of the powder average of a small number of coupled spins.⁴¹ Figure 2 shows the ^{19}F MQ coherence development for sodium triflate salt ($\text{NH}_4^+\text{CF}_3\text{SO}_3^-$) well dispersed in polyhydroxystyrene.¹⁹ Only the $n = 0, 2$, and -2 quantum orders have nonzero intensity under the even-selective MQ excitation employed. This is the same behavior

Figure 2 The ^{19}F zero quantum and +2 and -2 quantum intensities from an even-selective experiment on 2 wt.% $\text{NH}_4\text{CF}_3\text{SO}_3^-$ in poly(*p*-hydroxystyrene). The salt is well dispersed in the polymer, and thus its CF_3 group behaves as expected for $N = 3$. Oscillations are distinct at early τ and destructive interference leads to steady-state values at long τ . (Reproduced by permission of the American Chemical Society from Limb et al.¹⁹)

expected for an isolated network of three dipole coupled ^{19}F nuclei, where only even MQ orders with $|n| \leq 3$ develop. This result indicates that the average spacing between the salt anions is large, allowing its CF_3 group to act as an isolated $N = 3$ cluster. Note that this configuration can be represented by the density matrix shown in Figure 1. Furthermore, the development of ± 2 quantum coherence intensity indicates that the time average of the intraion dipole couplings is nonzero. Thus, the triflate anion is not reorienting rapidly and isotropically within the polymeric matrix.

Clear oscillations in the MQ intensities are initially observed in Figure 2, while steady state is approached at $\tau > 500$ ms. The observed long time values are 0.78 for the zero quantum coherence and 0.22 for the sum of the +2 and -2 quantum coherences. These values differ significantly from the predictions of equation (6a), utilizing $N = 3$ and $C = 2$, of 0.625 and 0.375, respectively. This difference shows that the statistical limit has not been achieved, a problem that was anticipated for very small numbers of coupled spins due the presence of symmetry disallowed MQ transitions. Thus, it is desirable to determine N for very small networks by detecting the highest order coherence present, rather than by assuming that the statistical limit holds.

For larger groups of spins, good agreement with the statistical limit behavior has been found. The liquid crystal, *p*-hexyl-*p*'-cyanobiphenyl ($\text{C}_{19}\text{H}_{21}\text{N}$) is a finite cluster of dipole coupled spins, since translation and anisotropic rotation serve to destroy intermolecular dipole couplings, while intramolecular dipole couplings maintain nonzero values. As expected, the positive order MQ coherences grow with τ until all the protons on the liquid crystal molecule are coupled on the experimental timescale. No further increase occurs as the preparation time increases further. The distribution of the steady state MQ intensities is well described by equation (6b)

with $N = 20 \pm 1$. This result is in excellent agreement with the known structural formula.³

Thus, MQ NMR gives quantitative information on the number of nuclei in a limited network of dipole, when the structure is unknown. For instance, the size of small hydrogenated defects in amorphous semiconductors has been determined.^{4–7} The clustering of molecules inside zeolites^{9,11–14} and the distribution of molecules on catalysts^{8,10,29} and on chromatographic supports¹⁵ have also been investigated using the MQ spin counting technique.

6 LARGE DIPOLE COUPLED NETWORKS

Although the MQ dynamics of spin systems for which the dipole coupling network extends beyond the typical 1–2 nm length scale of a MQ NMR experiment are nearly impossible to calculate exactly, similar development of $I_n(\tau)$ is observed in many samples. Figure 3 shows the development of positive even-order MQ coherence intensity for CaF_2 powder for increasing τ created from integral multiple repeats of t_c between 30 and 60 μs . The smooth MQ development in Figure 3 is a result of the distribution of dipole coupling present in this polycrystalline sample. Significant oscillations in $I_n(\tau)$ can be seen in a single crystal CaF_2 with its (111) direction oriented perpendicular to the applied magnetic field (Figure 4). For this configuration, all internuclear vectors to the nearest ^{19}F neighbors are at either 54.7° , the magic angle, or $(54.7 + 180)^\circ$. Thus, all four dipole couplings between nearest neighbors are zero for this configuration. The strongest couplings in this system are actually between next nearest neighbors. The lack of angular dispersion and relative weak dipole couplings lead to only slow damping of the oscillation of the MQ coherences which arises from the even weaker dipolar coupling to neighbors in other shells. The small dipolar couplings in the (111) oriented crystal also lead to slower growth of positive MQ intensities than is observed for the powdered CaF_2 sample.

The observed distributions of $I_n(\tau)$ for polycrystalline powders are often described empirically as a Gaussian distribution, as can be seen in Figure 5 for powdered CaF_2 and GaP , where the solid lines are given by equation (7). The slow development of MQ coherence intensity in GaP allows the comparison to be made for low $N(\tau)$ while CaF_2 provides information at higher $N(\tau)$ values. This description is convenient, as the single parameter $N(\tau)$ can be used to

Figure 3 Even-order selective ^{19}F MQ spectra of a polycrystalline powder of CaF_2 . As τ increases, high-order coherence intensities grow monotonically

Figure 4 Even-order selective ^{19}F MQ spectra of a single crystal of CaF_2 oriented with its (111) direction along the external magnetic field. The lack of angular orientation distribution, as compared to the powder (Figure 3), leads to oscillatory growth of the zero and two quantum coherences, while the smaller magnitude of the dipole couplings in this sample leads to slower higher order coherence growth

Figure 5 Gaussian distribution (—) and experimentally measured intensities versus $N(\tau)$ for two large dipole coupled networks, Ca^{19}F_2 (squares) and Ga^{31}P (other symbols), showing reasonable agreement for $N(\tau) < 70$: (■) I_0 , (□) I_2 , (▲) I_4 , (△) I_6 , (●) I_8 , (○) I_{10}

describe an entire MQ spectrum.² However, the interpretation of $N(\tau)$ via equation 6.76 is not straightforward, since the number of coupled spins is ill defined in this situation. Materials with the highest dipolar couplings also display the fastest growth of $N(\tau)$. Thus $N(\tau)$ has been considered as a parameter that is dependent on the size, structure, and motion of the dipolar coupling network.

Non-Gaussian behavior of the distribution of positive MQ orders for infinite spin systems at long τ has been noted, usually becoming significant when $N(\tau)$ is greater than about 70. In addition, a least-squares fit to equation (6) underpredicts the intensity of the nonzero orders while overpredicting the zero quantum intensity. This may indicate relaxation of intensity in the off-diagonal density matrix elements back to diagonal elements. These effects are not seen in the 21-spin system, liquid crystal *p*-hexyl-*p'*-cyanobiphenyl ($\text{C}_{19}\text{H}_{21}\text{N}$), experiments at similar τ , and thus cumulative pulse errors cannot be the sole cause of the deviation. Experimentally,

Figure 6 Effective number of correlated nuclei, $N(\tau)$ as function of τ for three-dimensional distributions (a): ($\square$) CaH_2 (^1H),³¹ (Δ) adamantane (^1H),³¹ ($\circ$) sodium bicarbonate (^1H),³¹ (+) GaP (^{31}P).²¹ (b) All ^{19}F :¹⁶ (+) CaF_2 , ($\blacktriangle$) NaAsF_6 , ($\bullet$) CsF , ($\blacksquare$) $(\text{C}_6\text{F}_5)_3\text{SAsF}_6$. (c) A universal MQ growth curve is seen for all the samples in (a) and (b), when a nondimensional time axis is created by multiplying τ by $M_2^{1/2}$ (equation (1))

the zero quantum intensity deviates from Gaussian behavior at the smallest number of correlated spins, making it a strong indicator of the onset of relaxation effects.

However, as shown in Figure 6(a) and 6(b) for $N(\tau) < 70$, $N(\tau)$ does grow as the MQ excitation time τ increases. This development of $N(\tau)$ can be described by a universal growth curve when a dimensionless MQ excitation time is created

by multiplying τ by $M_2^{1/2}$.^{18,21,31} The result of this scaling is shown in Figure 6(c), where $M_2^{1/2}$ has been calculated from equation (1) using the known crystal structures of the materials. The solids represented in Figure 6 fall into one of two categories. In both categories the dipolar field at each nucleus in a three-dimensional crystal lattice is equivalent and time independent on the MQ timescale. For the first class of materials, no translation or rotation occurs on the NMR timescale. Examples of this category include Ca^1H_2 , Ca^{19}F_2 , and Ga^{31}P . In the second class, rapid isotropic rotation exists in the absence of translation, allowing only intermolecular dipole couplings to survive. Examples of such behavior are ^1H in adamantane or ^{19}F in salts containing hexafluoroarsenate anions (AsF_6^-). For this second category, the high concentration of NMR active nuclei with relatively low dipole couplings allows larger numbers of spins to be correlated before relaxation effects become significant.

The MQ dynamics of many molecular solids do not follow the universal growth curve, since these solids possess a variety of short internuclear spacings and motion which is neither fast nor isotropic. Sometimes, lowering the sample temperature can eliminate such undesirable motion. In addition, some nuclear distributions are inherently nonuniform, and non-Gaussian intensity distributions are observed even at short τ . For example, both isolated salt molecules and salt aggregates can exist within the same salt/polymer mixture.^{17,19} The fraction of each environment can be quantitated by treating the observed MQ spectra as a linear combination of the two MQ intensity distributions. Treatment of MQ coherence growth from nuclei within tightly coupled clusters in addition to slower intercluster growth has also been used to analyze proton distributions in amorphous hydrogenated semiconductors^{4–7} and to characterize the distribution of molecules absorbed in zeolites.^{11,12}

7 DIMENSIONALITY OF A NUCLEAR SPIN DISTRIBUTION

Certain deviations from the MQ universal behavior [Figure 6(c)] for large dipole coupled networks cannot be accounted for by the presence of molecular motion. Such deviations may indicate that the nuclear distribution is not three dimensional. Hydrogen existing on the surface of a treated natural diamond powder is an example of a two-dimensional distribution.³¹ For the diamond powder, the $N(\tau)$ versus τ curve exhibits a concave upward shape, unlike $N(\tau)$ for the 21-spin liquid crystal, which saturates at large preparation times. Thus, the diamond powder represents a large dipole coupled network. However, its MQ growth does not follow the universal scaling behavior of the three-dimensional model compounds. Even greater deviation from the universal curve was found for the initial MQ growth among protons in hydroxyapatite which provides a pseudo-one-dimensional distribution of spin- $\frac{1}{2}$ nuclei.³³

To predict the influence of dimensionality on the rate of MQ coherence in large dipolar networks, a solution to equation (4) is required. For this purpose $\hat{\rho}(\tau)$ is expanded in terms of product operators, as an alternative to tracking the time development of each of the 4^N individual elements.⁴¹ These product operators are formed from the multiplication

of individual spin operators ($\hat{I}_{iz}$, $\hat{I}_{i+}$ or $\hat{I}_{i-}$) from M of the N nuclei in the dipole network. For example, $\hat{I}_{5z}\hat{I}_{6-}\hat{I}_{7+}\hat{I}_{8z}$, represents $M = 4$ possible product operators when $N \geq 8$.

Two simplifications³¹ allow $\hat{\rho}(\tau)$ to be approximated by an expansion requiring only N coefficients:

$$\hat{\rho}(\tau) \approx \sum_{M=1}^N C_M(\tau) \hat{P}_M \quad (11)$$

Here, $\hat{P}_M$ is a time independent average product operator, representing all the possible product operators containing M spins. Thus, the time evolution of the MQ coherence and multiplicity of all possible product operators with respect to M is contained in the coefficients $C_M(\tau)$.

When $\hat{\rho}(0) = \hat{I}_z$, only $C_1(0)$ has nonzero intensity. Intensity develops in C_M for $M > 1$ with increasing τ through the commutator obtained when equation (11) is substituted into equation (4) under excitation by $\hat{\mathcal{H}}_{yx}$:

$$\begin{aligned} \sum_M \left(\frac{dC_M}{d\tau} \hat{P}_M \right) \\ = \frac{-i}{4} \sum_M C_M \left\{ \sum_i \sum_{j \neq i} R_{ij} [\hat{P}_M, (\hat{I}_{i+}\hat{I}_{j+} - \hat{I}_{i-}\hat{I}_{j-})] \right\} \quad (12) \end{aligned}$$

This summation represents only N coupled differential equations, thus significantly reducing the volume of calculation required compared to the exact solution. Information on the order of the MQ coherences has been averaged away. However, approximating the effective spin correlation size $N(\tau)$ as the center of mass of the distribution of C_M over M allows the results of the average product operator model to be compared directly with experimental measurements of $N(\tau)$.³¹

To emphasize that the rate of MQ coherence development through equation (12) is strongly dependent on the geometry of the dipole coupled network, only two values of R_{ij} will be considered. All nearest neighbor dipole couplings are taken to be equal to the root-mean-square value over the powder average for the nearest neighbor separation, and all R_{ij} for all non-neighboring nuclei are set equal to zero. This is a stepwise approximation to the true decay in the magnitude of dipole coupling constants with internuclear distance cubed.

Because R_{ij} is nonzero only for nearest neighbors, only product operators representing M spins occupying a contiguous region of space will contribute to the average product operator $\hat{P}_M$. For simplicity, lines, squares, and cubes are the shapes assumed to be associated with $\hat{P}_M$ for nuclei distributed uniformly over one-, two-, and three-dimensional lattices, respectively. A schematic drawing of $\hat{P}_9$ for a two-dimensional (surface) distribution of nuclei is shown in Figure 7. In order to compute MQ dynamics, the commutator in equation (11) must be evaluated. Only adjacent i, j spin pairs need to be considered because only these have nonzero values of R_{ij} . Thus, the larger the number of nearest neighbors, the greater the possibilities for high-order MQ development. As shown in Figure 7, the spin pair i, j and the M spins comprising $\hat{P}_M$ will have zero, one, or two of their spins in common; these cases correspond to pairs external to, at the surface of, or internal to $\hat{P}_M$, respectively. The commutator for external pairs is

Figure 7 Schematic drawing of $\hat{P}_M$, the average product operator for nine spins on a two-dimensional square lattice. Surface pairs lead to forward MQ growth, while internal pairs reduce the coherence size. Faster MQ coherence growth rates are anticipated as the dimensionality of the lattice increases, since the ratio of surface pairs to internal pairs increases

identically zero, resulting in no change in the size of the MQ coherence. Products of $M + 1$ and $M - 1$ spin operators result from commutators involving surface and internal pairs, respectively.

The $\hat{P}_{M+1}$ operators represent forward growth of the MQ coherence size, while the $\hat{P}_{M-1}$ operators correspond to reverse growth, allowing equation (12) to be simplified to

$$\begin{aligned} \sum_M (dC_M/d\tau) \hat{P}_M = \frac{-i}{4} \sum_M C_M \\ \times (W_{M+1}^f \hat{P}_{M+1} + W_{M-1}^r \hat{P}_{M-1}) \quad (13) \end{aligned}$$

Note that the $\Delta M = \pm 1$ selection rule for product operator evolution under $\hat{\mathcal{H}}_{yx}$ is evident from this equation. The forward and reverse growth rate coefficients W_M^f and W_M^r depend on the number of pairs at the surface of and internal to $\hat{P}_M$. Since the surface-to-volume ratio for $\hat{P}_M$ depends on its dimensionality, higher MQ growth rates are anticipated for homogeneous distributions of nuclei of increasing dimensionality.

Thus, using average product operators, an N -spin system can be represented by a set of N simultaneous differential equations, allowing the MQ dynamics of large numbers of spins, arranged in varying morphologies, to be easily simulated. Figure 8 shows the growth of $N(\tau)$ predicted by the average product operator model using only nearest neighbor couplings of 1.0 kHz. The analytical formulae used to calculate W_M^f and W_M^r in equation (13) are given in Levy and Gleason.³¹ The three curves were obtained by considering 2500 nuclei arranged uniformly on linear, square, or cubic lattices. As expected, the three-dimensional configuration of nuclei yields the fastest MQ growth. The linear geometry yields slow linear growth of $N(\tau)$. The model can be used to simulate the MQ dynamics of various types of spin distribution and has been extended to nuclear distributions having more than one characteristic nearest neighbor dipole coupling.³¹

The model and experimental data can be compared by scaling the time axis in Figure 7. The experimental data for CaH_2 and for hydrogenated diamond powder given in Figure 9 are in good agreement with the computer simulations of MQ coherence growth for two- and three-dimensional nuclear distributions based on the average product operator

Figure 8 Values of $N(\tau)$ predicted by the average product operator model for spin- $\frac{1}{2}$ nuclei evenly spaced on a line, square lattice, or cubic lattice. In each case, the nearest neighbor dipole coupling was fixed at 1 kHz. The most rapid growth of $N(\tau)$ results for the cubic lattice which has the largest number of nearest neighbors, while the linear arrangement, with the lowest number of nearest neighbors, yields the slowest development of $N(\tau)$. model with only one adjustable parameter. In addition, the initial MQ growth of the pseudo-one-dimensional distribution of protons in hydroxyapatite has been found to agree with the slow, nearly linear growth predicted by the results of the product operator calculation for the one-dimensional distribution of nuclei.³³

8 RELAXATION AND EFFECT OF MOLECULAR MOTION

MQ relaxation rates have been considered in detail by Ernst in terms of the Redfield formalism.³⁵ The zero quantum and

Figure 9 Comparison of MQ dynamics predicted by average operator theory and experimental data for infinite two- and three-dimensional systems. (Reproduced by permission of the American Chemical Society from Levy and Gleason³⁰)

$n \geq 2$ MQ relaxation rates provide information on the spectral densities of autocorrelation and cross-correlation functions which is not obtainable from the more traditionally measured single quantum relaxation rates. Since the sensitivity to static magnetic field inhomogeneity is proportional to the MQ order, this effect can be problematic when measuring higher order MQ relaxation rates. However, zero quantum relaxation rates have the desirable property of not being influenced by such gradients. This exact theoretical treatment of MQ relaxation has been applied to the external paramagnetic relaxation of two spin- $\frac{1}{2}$ nuclei in a liquid³⁵ and of an oriented CH_3 group in a liquid crystal.³⁶ However, application of this exact theory becomes increasingly difficult as the size of the coupled spin- $\frac{1}{2}$ network increases and when the results must be averaged over many possible orientations. Thus, although general considerations have been addressed,^{23,28} the measurement and quantitative analysis of MQ relaxation in polycrystalline solids have been limited to date.

Empirically it has been observed that the total signal present in the detection period after MQ excitation of a rigid solid decreases with τ , often becoming negligible for $\tau > 1$ ms. The largest number of spins correlated is thus generally limited to between 100 and 1000, corresponding to a 1–2 nm length scale in a bulk three-dimensional solid. In addition, models for the growth of MQ coherence are difficult to validate because spin correlation data are generally only available for relatively very short τ .

Additional effects are observed when molecular motion modulates the dipolar couplings in solids through variations in internuclear distances and/or the orientation of the internuclear vectors with respect to the applied magnetic field.²⁰ When the timescale for motion is comparable to τ , complete time reversal of the preparation period is not achievable during the mixing period. Thus, the fraction of magnetization which is actually refocused by the MQ experiment f_{MQ} will generally be < 1 . However, efficient refocusing can occur if the frequency of the molecular motion and the MQ experiment are matched correctly. Since τ is generally between 30 μs and 1 ms, motions with frequencies between 1 and 33 kHz can be probed. Since MQ coherences can involve anywhere from 2 to >100 nuclei, the correlated motion for atomic groups of various sizes can be probed, rather than tracking the motion of a single site.

As temperature is monotonically increased and the MQ preparation time is fixed, the frequency of motion can take on several of these special refocusing frequencies, interspersed by defocusing frequencies. Thus, a series of oscillations in f_{MQ} with temperature is expected. In addition to identifying the frequency of motion, the shapes of these oscillations are signatures of the underlying mechanism of molecular motion, e.g. multisite hops versus continuous rotations. Only motions which restore the relative positions of the nuclei after the MQ experiment will cause refocusing. Motions, such as translational diffusion, which do not restore the initial configuration of the nuclei will not produce refocusing under any condition.

Figure 10 shows the temperature dependent ^{19}F f_{MQ} for two polytetrafluoroethylene samples of different crystallinity.¹⁹ Each line indicates a fixed value of the MQ preparation period τ . The overall decrease in f_{MQ} with increasing τ indicates that relaxation is not associated with molecular motion. However, at each fixed τ , oscillations in f_{MQ} can be seen. Oscillations in

Figure 10 The fraction of refocused magnetization, f_{MQ} at three different values of τ as a function of temperature for *as*-polymerized (■, ▲, ●, —) and melt-crystallized (□, ○, △, - - - -) polytetrafluoroethylene. Oscillations are seen only in the *as*-polymerized polymer, corresponding to the motion of a point defect

f_{MQ} are observed from 208 to 230 K for the 98% crystalline sample, while this ratio is constant over the same temperature range for the 64% crystalline sample. These oscillations may be associated with paracrystalline defects found only in the first sample. Thus, the MQ refocusing experiment is able to differentiate clearly between polymer samples which have different thermal histories. The sharpness of the MQ refocusing features and their variations in magnitude, shape, and sign with temperature are signatures of the molecular level details of the underlying dynamics which produce them.

1 INTRODUCTION

A majority of magnetically active nuclides in the Periodic Table possesses half-integer spin numbers: $S = 3/2, 5/2, 7/2$ and $9/2$ (Figure 1).¹ Unlike their more common spin-1/2 counterparts, these nuclei possess quadrupole moments and thus interact not only with external or internal magnetic fields, but also with the electric field gradients (EFG) originating from asymmetries in the distribution of charges that surrounds them.^{2,3} Depending on the degree of distortion in this local charge distribution, the resulting quadrupole couplings can be small or large when compared to the Zeeman coupling ν_0 between the nuclear magnetic moment and the external magnetic field B_0 . If sufficiently small, quadrupole effects can often be neglected and the NMR of the spins treated as their $S = 1/2$ counterparts;⁴ if comparatively large NMR observations are seldom successful and zero-field nuclear quadrupole resonance (NQR) analyses become the alternative of choice.³ By contrast to these cases, the majority of scenarios, including those to be considered here, are those where quadrupolar couplings are sizable yet still enable the acquisition of solid state NMR spectra. The resulting quadrupole couplings can then be treated as minor perturbations to a main Zeeman interaction; this leads to broadenings that to first order are orientation-dependent and proportional to the square of the z component of the angular momentum S_z .² For moderately strong quadrupole couplings this implies that when analyzing powdered or disordered samples, all the allowed $\Delta S_z = \pm 1$ transitions will be broadened beyond the NMR detection limit except for the

central $-1/2 \leftrightarrow 1/2$ one. It is consequently on these central transitions, which end up being much sharper than the remaining single-quantum signals in the spin manifold, that most solid state NMR studies of half-integer quadrupolar nuclei are generally focused.

In spite of this consideration, central transition quadrupolar NMR spectra do not generally render sharp resonances from powdered samples. This is due to the presence of residual second order quadrupolar broadenings.^{2–6} Such higher order effects are proportional to the square of the internal perturbation divided by the main Zeeman interaction, and therefore usually negligible in $S = 1/2$ cases involving shielding or dipolar couplings. They will, however, affect half-integer quadrupoles to an extent proportional to the (quadrupole coupling)²/ ν_0 , broadening their central transitions resonances by tens or hundreds of kilohertz whenever EFGs are significant. Analyzing the resulting second order quadrupolar line shapes is not inherently difficult when dealing with individual chemical sites,⁴ yet overlap among inequivalent powder patterns precludes these analyses if several inequivalent sites are present. An improvement in the resolution of these solid state line shapes can be achieved by variable-angle sample spinning.^{7–9} Yet by contrast to the spin-1/2 case, where first order anisotropies such as the chemical shielding or dipole–dipole interaction can be successfully removed via fast magic angle spinning (MAS), no single ‘magic’ spinning angle exists capable of removing all the second order effects originated by quadrupolar couplings. This complication stood out as one of the main limitations in the application of solid state quadrupolar NMR, particularly when it came to characterizations of complex materials such as minerals, catalysts, ceramics and glasses.¹⁰

A better understanding of the nature of second order quadrupole effects has changed this state of affairs. During recent years, a number of different averaging procedures have been proposed, capable of achieving the long-sought goal of bringing high resolution NMR to quadrupolar nuclei.^{11–14} All these techniques have in common the introduction of an additional degree of freedom in the manipulation of the spins’ evolution; manipulating this extra variable then enables the refocusing of residual second order anisotropies, usually in a two-dimensional (2D) NMR fashion. One approach for implementing such high resolution acquisitions is based on the use of multiple quantum (MQ) spectroscopy in combination with conventional MAS. The resulting technique became known as multiple quantum magic angle spinning (MQMAS),^{14,15}

Figure 1 Periodic Table of the Elements indicating the nature of the most abundant NMR-active isotopes. Notice the predominance of half-integer quadrupolar species

and thanks to its ease of implementation it quickly became a method of choice for studies of quadrupolar nuclei in powdered samples. The present article summarizes basic theoretical and practical aspects of MQMAS, as well as limitations to its resolution performance. In its conclusions it also reflects on some of the challenges opened up by the development of this technique.

2 SECOND ORDER QUADRUPOLE EFFECTS: ORIGINS AND AVERAGING APPROACHES

2.1 Second Order Quadrupole Effects

Just as their spin-1/2 counterparts, quadrupolar nuclei possess magnetic moments through which they can interact with magnetic fields. These include the external field B_0 , pulsed radiofrequency (rf) fields B_1 , local fields generated by the chemical shielding as well as by the dipolar moments of other nuclei. Such magnetic couplings are usually represented by quantum mechanical Hamiltonians: H_Z , H_{RF} , H_{CS} , H_D . In addition, nuclei with $S > 1/2$ are distinguished by a nonspherical shape (Figure 2), associated with a nuclear quadrupole moment capable of coupling with the surrounding electric field gradients. The result is a quantum-mechanical Hamiltonian H_Q that may also end up affecting the NMR transitions. All these local Hamiltonians can be represented by scalar products of spatial and spin tensors of rank $k \leq 2$:^{16,17}

$$H_\lambda = C_\lambda \bar{\bar{R}} \cdot \bar{\bar{T}} = C_\lambda \sum_{k=0}^2 \sum_{m=-k}^k (-1)^m R_{k-m}^{(\lambda)} T_{km}^{(\lambda)} e^{-im\omega_0 t} \quad (1)$$

where $R_{k-m}^{(\lambda)}$, $T_{km}^{(\lambda)}$ define the spatial and spin components of the Hamiltonian, and C_λ is the corresponding coupling constant. Except for $m = 0$ the matrix representation of the T_{km} spin operators is off-diagonal in the usual basis set of Zeeman eigenstates $\{|S_z\rangle\}_{-S \leq S_z \leq S}$. Consequently, analyzing the effects of arbitrary internal Hamiltonians in the presence of the Zeeman coupling is a complex task not always susceptible to analytical treatment. This problem can be simplified when it is possible to assume that all internal interactions H_λ act only as minor perturbations to the main Zeeman coupling. To first order this approximation allows one to consider only those terms that commute with H_Z , which in turn is proportional to T_{10} . Since all internal anisotropies possess rank $k = 2$ this implies that only T_{20} contributions remain. For the

Figure 2 Origin of the electrostatic quadrupole interaction in spins $S \geq 1$, arising from placing the ellipsoidal nuclear positive charge into local electrostatic field gradients. The ensuing coupling ends up depending on the moments of the nucleus, which according to the Wigner–Eckart theorem are in turn proportional to the quantum operators $\{S_\alpha\}_{\alpha=x,y,z}$

quadrupolar Hamiltonian, the resulting first order coupling can be written as

$$H_Q^{(1)} = C_Q R_{20}^{(Q)} T_{20}^{(Q)} = C_Q \sqrt{\frac{1}{6}} R_{20}^{(Q)} [3S_z^2 - S(S+1)] \quad (2)$$

where $C_Q = \frac{e^2 q Q}{4S(2S-1)\hbar}$ defines the strength of the nuclear quadrupole coupling to the surrounding EFG, and $R_{20}^{(Q)}$ is an irreducible second-rank spherical tensor element depending on the relative orientation between the quadrupole tensor of a given site in a particular crystallite and the Zeeman field. A similar orientation dependence characterizes other first order effects like the dipolar or the chemical shift anisotropies. In principle, all of these anisotropies are susceptible to averaging when executing fast MAS at rates $\nu_r \gg C_\lambda$. Indeed upon mechanical spinning the sample all R_{20}^λ will acquire a time dependence whose average is^{3,7,18}

$$\langle R_{20}^\lambda(t) \rangle = R_{20}^\lambda \cdot P_2(\cos \chi) \quad (3a)$$

where

$$P_2(\cos \chi) = \frac{3 \cos^2 \chi - 1}{2} \quad (3b)$$

is the second order Legendre polynomial possessing a root at $\cos \chi = 1/\sqrt{3}$. Setting the spinning axis at the magic angle $\chi = 54.7^\circ$ with respect to B_0 effectively nulls this geometric scaling factor, thereby removing all anisotropic contributions to the solid NMR Hamiltonian.

Achieving such a fast spinning regime in quadrupolar cases is actually difficult in a majority of nuclei by virtue of the large size of their quadrupole moments. Even so, it is possible to avoid the effects of first order quadrupolar anisotropies thanks to the T_{20} -type dependence that characterizes these effects [equation (2)]. The S_z^2 factor in T_{20} then frees the $-1/2 \leftrightarrow +1/2$ transition of first order quadrupolar influences, and is in turn the reason why half-integer quadrupolar studies have generally focused on this central transition.

In spite of this consideration, central transition experiments do not generally afford well resolved resonances. This is due to the large magnitudes of the quadrupolar couplings usually involved, which do not justify the neglect of higher order effects. Particularly important to consider are the second order corrections that the full quadrupolar Hamiltonian will impart onto the spin energy eigenvalues. Standard perturbation theory enables one to represent these effects by⁵

$$H_Q^{(2)} = \frac{C_Q^2}{\nu_0} \sum_{m \neq 0} \frac{R_{2m}^{(Q)} R_{2-m}^{(Q)} [T_{2m}, T_{2-m}]}{2m} \quad (4a)$$

$$H_Q^{(2)} = -\frac{C_Q^2}{2\nu_0} \left\{ \begin{aligned} &R_{2-1}^{(Q)} R_{21}^{(Q)} S_z [4S(S+1) - 8S_z^2 - 1] \\ &+ R_{2-2}^{(Q)} R_{22}^{(Q)} S_z [2S(S+1) - 2S_z^2 - 1] \end{aligned} \right\} \quad (4b)$$

These correction terms are proportional to the square of the quadrupolar couplings scaled by Zeeman interaction, hence leading to the C_Q^2/ν_0 dependence characteristic of second order effects. The multiplication of quadrupolar terms in equation (4) also leads to spatial components that transform as *products* of second-rank spherical tensor elements, as opposed to the simpler R_{20} dependence that characterized all first order

effects. Such products result from taking cross correlations of the quadrupolar interaction with itself, and imply that line shapes derived from $H_Q^{(2)}$ will be affected by a net isotropic quadrupolar shift ν_Q^0 even though H_Q 's original center of mass was zero for all transitions. Also worth mentioning are the products involved in the T_{2m} commutators; these endow $H_Q^{(2)}$ with a spin-space dependence that is different from either T_{10} (linear in S_z) or T_{20} (quadratic in S_z), a feature that will eventually enable MQMAS to refocus second order effects via spin-space manipulations which do not simultaneously remove all chemical shift information.

The presence of isotropic quadrupolar shifts provides a mechanism for distinguishing among chemically inequivalent sites acting in addition to the usual isotropic chemical shift. The anisotropic character of $H_Q^{(2)}$, however, implies that sites in a powder will now also show broad line shapes even when focusing on the central transitions. Furthermore, by contrast to what happened with first order effects, fast MAS of the sample will then be of limited use for assisting in the narrowing of these powder patterns. This is a consequence of the higher complexity associated with the spatial terms of $H_Q^{(2)}$, involving products of second-rank tensors and thus giving origin to both second- (R_{20}) and fourth-rank (R_{40}) anisotropies. The former transform in the usual $P_2(\cos \chi)$ fashion and can thus be removed by MAS; the latter by contrast scale upon sample spinning as the fourth-rank Legendre polynomial $P_4(\cos \chi) = (35\cos^4 \chi - 30\cos^2 \chi + 3)/8$, which can be set to zero at some spinning angles but not when $\chi = 54.7^\circ$ (Figure 3). The noncoincident roots of these two polynomials implies that no single choice of spinning axis will simultaneously remove all second order quadrupolar broadenings from a central transition spectrum.^{5,11,19}

2.2 Alternatives to Refocus the Anisotropies

One way of remedying this single-axis spinning deficiency is by introducing more complex forms of mechanical reorientation; for instance, by consecutively spinning the sample

Figure 3 Orientation dependence of the two Legendre polynomials $\{P_l(\cos \chi)\}_{l=2,4}$ that define the line broadening of central transition quadrupolar patterns. Also shown are the positions of the polynomials' roots: $\chi_m = 54.7^\circ$, the usual magic angle for averaging second-rank anisotropies, and $\chi = 30.6^\circ, 70.1^\circ$ for the fourth-rank anisotropies that show up on considering second order effects. The presence of two anisotropic contributions whose zeroes do not coincide deprives sample spinning from the possibility of averaging away central transition broadenings

about two different spinning axes. The two sample spinning angles (χ_1, χ_2) will then be associated with corresponding evolution times (t_1, t_2), bringing in turn the idea and the possibility of refocusing anisotropies via a bidimensional (2D) NMR approach. The choice of spinning angles in these dynamic angle spinning (DAS) experiments demands the simultaneous cancellation, at a given time and for all crystallites in the powder, of both the second- and fourth-rank anisotropies arising from the second order effects. It follows from the considerations above that this can be achieved when setting^{11,13}

$$\begin{aligned} P_2(\cos \chi_1)t_1 &= -P_2(\cos \chi_2)t_2 \\ P_4(\cos \chi_1)t_1 &= -P_4(\cos \chi_2)t_2 \end{aligned} \quad (5)$$

conditions which do not affect the normal course of the isotropic evolution. At the conclusion of the total $t_1 + t_2$ evolution time, this choice of spinning angles will lead to the formation of an echo signal encoding a purely isotropic evolution, and by synchronous increases in the duration of (t_1, t_2), this procedure can end up affording a high resolution time-domain signal. This stepwise t_1, t_2 refocusing is different from that occurring in MAS, where anisotropies are being continuously removed. Indeed, in DAS, anisotropies are not removed but show up, after Fourier transformation of the 2D time domain signal, correlated along a sharp ridge for each site in the sample. Therefore unlike MAS, DAS does not bring with its higher resolution an effective increase in signal-to-noise; in fact, signal will be lost by virtue of the need for storing the evolving coherences along B_0 while the spinning axis is mechanically reoriented from χ_1 to χ_2 .

A refocusing similar to that carried out by DAS but involving a single axis of sample rotation is feasible if the restriction to central transition observations is lifted. Indeed it follows from the arguments given earlier that for any half-integer quadrupole nucleus not only the central but in fact any $S_z = -m \leftrightarrow S_z = +m$ MQ transition will be free from the dominant first order quadrupole broadenings (Figure 4). Yet these transitions will still be affected by second order quadrupole effects, opening up the possibility of compensating the residual broadenings affecting their line shapes with those arising in the central $-1/2 \leftrightarrow +1/2$ transition. To explore such a possibility it is necessary to incorporate the transition order m into the explicit description of the second order NMR frequencies. Under rapid sample spinning conditions this calculation leads to the angle- and order-dependent evolution frequency

$$\begin{aligned} \nu_Q^{(2)}(m, \chi) &= A_0^Q C_0^S(m) + A_2^Q(\varphi, \theta) C_2^S(m) P_2(\cos \chi) \\ &\quad + A_4^Q(\varphi, \theta) C_4^S(m) P_4(\cos \chi) \end{aligned} \quad (6)$$

where the $\{A_l^Q\}_{l=0,2,4}$ denote the isotropic, second- and fourth-rank quadrupolar contributions, and the $\{C_l^S(m)\}_{l=2,4}$ are polynomials which depend on the spin S and transition order m involved:

$$C_0^S(m) = 2m[S(S+1) - 3m^2] \quad (7a)$$

$$C_2^S(m) = 2m[8S(S+1) - 12m^2 - 3] \quad (7b)$$

$$C_4^S(m) = 2m[18S(S+1) - 34m^2 - 5] \quad (7c)$$

Figure 4 Hierarchical energy level diagram for an $S = 3/2$ nucleus interacting with a dominating external magnetic field coupling and an electric field gradient perturbation

Equation (6) shows the analogous roles that spinning angles and quantum numbers play in defining the second order evolution frequency: the former will scale anisotropies according to the $\{P_l(\cos \chi)\}_{l=2,4}$ polynomials, the latter according to the $\{C_l^S(m)\}_{l=2,4}$ coefficients. Thus instead of fixing m at $1/2$ and using χ as a degree of freedom as is done in DAS, it is possible to propose a 2D refocusing experiment whereby for a fixed spinning angle χ spins evolve during initial and final times t_1 , t_2 under the effects of two different transition orders m_1 and m_2 (Figure 5). $H_Q^{(2)}$ -driven anisotropies will then dephase both of these coherence orders along their respective evolution times, but since these anisotropies can be made proportional to one another for every crystallite the result of such 2D correlation will be powder line shapes that show up as sharp parallel ridges for different sites in the sample.

In analogy to equation (5), the spectral correlation of anisotropic broadenings that is introduced by this MQ strategy can be associated with the time-domain refocusing conditions

$$C_2^S(m_1)t_1 = C_2^S(m_2)t_2 \quad (8a)$$

$$C_4^S(m_1)t_1 = C_4^S(m_2)t_2 \quad (8b)$$

At this (t_1, t_2) point in the MQ correlation, a purely isotropic signal can be detected, which if Fourier transformed would lead to a 1D high resolution NMR spectrum. Although a range of spinning angles χ are compatible with equations (8a,b), the most convenient choice is naturally $\chi_{MAS} = 54.7^\circ$, since under these conditions the hitherto neglected chemical shift and dipolar anisotropies will also be effectively averaged away by the spinning. Simultaneously, MAS makes the second-rank refocusing condition (equation (8a)) immaterial. The selection rules for NMR also need to be considered at this point; these state that in the directly detected domain only single quantum coherences can yield measurable signals, restricting the coherence order to be employed during t_2 to $m_2 = 1/2$; the central single quantum transition. As for the choice of m_1 this may in principle be dictated by the spin number (for $S = 3/2$ only $m_1 = 3/2$ is available; for $S = 5/2$ only $m_1 = 5/2$, etc.); yet in all cases at least one such MQ transition is available, and it is the indirect domain that will encode its evolution. Standard phase cycling procedures

Figure 5 (Top) Schematic diagram of the MQMAS pulse sequence. (Bottom) 2D diagram illustrating how the proportionality among second order MAS broadenings in both the central and MQ transitions, enables high resolution acquisitions when data are considered at appropriate angles in the $MQ \rightarrow 1Q$ 2D correlation spectrum

also put under the experimentalist's control the apparent sense of evolution of the spins during t_1 ;²⁰ enabling the stepwise refocusing of all fourth-rank anisotropies regardless of the relative sign of the $C_4^S(m_1)$, $C_4^S(1/2)$ coefficients. As a result of all these considerations, it follows that in MQMAS, second order anisotropies will refocus for all crystallites in the sample simultaneously, at times fulfilling the condition

$$t_2 = \left\{ \frac{|C_4^S(m_1)|}{C_4^S(1/2)} \right\} t_1 \quad (9)$$

The appearance of such long-lived echoes at these particular (t_1, t_2) combinations is one of the most basic features displayed by MQMAS experiments. Their formation is illustrated in Figure 6 for a variety of S and m_1 cases, using ^{23}Na (spin-3/2) and ^{55}Mn (spin-5/2) MQMAS NMR examples. Rapidly decaying anisotropic evolutions are evident here along both the MQ and 1Q (t_1 and t_2) domains, yet as predicted by equation (9), a much slower decay is noticed along the ideal $|C_4^S(m_1)|/C_4^S(1/2)$ slope.

The capacity of MQMAS NMR to resolve chemically inequivalent sites is further illustrated in Figure 7(a), which shows how this experiment can distinguish four inequivalent ^{23}Na sites that overlap in the conventional MAS spectrum of the Na_2ATP complex. As in the DAS case, it may be convenient to transform the tilted powder patterns that result from these MQMAS experiments into a format that can yield a 1D high resolution trace by conventional projection. This can be done by a shearing transformation defined by the $|C_4^S(m_1)|/C_4^S(1/2)$ ratio; which is in essence a rotation of the line shapes, and can be carried out in such a way as to leave a conventional MAS pattern along one of the

Figure 6 ^{23}Na ($S = 3/2$) and ^{55}Mn ($S = 5/2$) MQMAS NMR time-domain data illustrating the formation of long-lived isotropic echoes at the theoretically expected slopes. (a, b) Triple- to single-quantum correlation experiments; (c) five- to single-quantum correlation experiment

Figure 7 2D 7.1 T ^{23}Na NMR spectrum arising from the $\text{Na}_2\text{ATP} \cdot 10\text{H}_2\text{O}$ complex crystallized from water/dioxane after (a) standard FFT of the 3QMAS time-domain data; (b) subjecting the 2D MQMAS data to a shearing transformation. In both cases the 1Q domain contains the conventional MAS line shapes, distorted by the relative powder efficiencies of the MQ excitation and conversion processes. Sites in (a) appear resolved when regarded at a slope depending on the $|C_4(3/2)/C_4(1/2)|$ ratio; in (b) by contrast, a projection along the indirect domain leads to a purely isotropic high resolution 1D dimension showing four partially resolved resonances (adapted from Ref.⁷⁴)

spectral axes and only isotropic components along the other (Figure 7b). An alternative procedure involves redefining the first evolution period so as to contain all the MQ evolution plus the fraction of 1Q evolution needed for a complete refocusing of anisotropies; such a redefined t_1 time will thus encode a purely isotropic evolution.²¹ Pros and cons involved in these and other MQMAS procedures are described in greater detail in the article by Pruski and Amoureux (see **MQMAS Advances**). Also worth noting is a recently proposed alternative whereby second order effects of the central 1Q transition are refocused not by symmetric MQ transitions, but by their single-quantum counterparts in the satellite

transitions²² (see **Satellite Transition NMR Spectroscopy of Half-Integer Quadrupolar Nuclei under Magic-Angle Spinning**).

3 MQMAS NMR PULSE SEQUENCES

3.1 General Considerations

The previous section introduced some of the problems associated with the acquisition of high resolution NMR spectra in the presence of second order effects, and the manner by which MQMAS enables the removal of the anisotropies via the

stepwise refocusing of MQ dephasings by 1Q spin evolutions. Two active steps are required for the generation of the ensuing MQMAS echoes: a first one involving the excitation of the MQ coherence starting from an equilibrium state, $S_z \rightarrow S_{x,y}^{MQ}$, and a second one involving the conversion of MQ coherences that evolved during t_1 into 1Q coherences whose signals can be detected: $S_{x,y}^{MQ} \rightarrow S_{x,y}^{1Q}$. Several pulse sequences have already been proposed to implement these two steps while undergoing MAS,^{14,15,21,23–48} and it is likely that new and better protocols to achieve these goals will continue to arise in the near future. Therefore in an effort to avoid premature obsolescence, this section focuses on general considerations of what such pulse sequences incorporate rather than on their comprehensive individual descriptions.

Before going into specifics, it is worth dwelling on generalities about what a good MQMAS pulse sequence should achieve. As manipulations of MQ coherences by means of rf fields are to first order forbidden by the conventional NMR transition rules, the excitation of MQ coherences and their subsequent transformation into 1Q observables is rarely a very efficient process. Hence if summarizing the initial excitation of MQ coherences according to

$$S_z \xrightarrow{\text{excitation}} e_x S_x^{MQ} + e_y S_y^{MQ} \quad (10a)$$

and the subsequent conversion process by

$$\begin{aligned} S_x^{MQ} &\xrightarrow{\text{conversion}} c_{xx} S_x^{1Q} + c_{xy} S_y^{1Q} \\ S_y^{MQ} &\xrightarrow{\text{conversion}} c_{yx} S_x^{1Q} + c_{yy} S_y^{1Q} \end{aligned} \quad (10b)$$

one of the main goals usually being sought in MQMAS is simply the maximization of the excitation $\{e_i\}_{i=x,y}$ and the conversion $\{c_{ij}\}_{i,j=x,y}$ coefficients. Furthermore the free spin evolutions occurring during t_1 and t_2 are unitary processes involving relatively long spin–spin relaxation decays which preserve the norm of the spin coherences; it is then convenient to introduce a description of the MQMAS signal intensity in terms of a single complex number $\varepsilon = (\varepsilon_x, \varepsilon_y)$ given by⁴²

$$\begin{aligned} \varepsilon_x &= [e_x(c_{xx} + c_{yy}) + e_y(c_{yx} - c_{xy})]; \\ \varepsilon_y &= [e_x(c_{xy} + c_{yx}) + e_y(c_{xx} - c_{yy})] \end{aligned} \quad (11)$$

The MQ processes in equations (10a,b) are usually mediated by the simultaneous action of the rf plus the orientation dependent first order quadrupole interaction, and therefore all coefficients in equation (11) will vary from crystallite to crystallite. In view of this, it becomes meaningful to associate an efficient MQMAS sequence with the largest powder averaged value of $|\varepsilon|^2$

$$|\varepsilon|^2 \approx \left\{ \left[\int_{\text{powder}} d\Omega \varepsilon_x(\Omega) \right]^2 + \left[\int_{\text{powder}} d\Omega \varepsilon_y(\Omega) \right]^2 \right\} \quad (12)$$

Yet it also follows from this analysis that there is more to an optimum pulse sequence than achieving the largest possible $|\varepsilon|^2$ value. This stems from the echo character of the MQMAS experiment, which requires all spins to evolve solely from the second order effects active during t_1 and t_2 . Conspiring against this requirement is the fact that both the rf-driven excitation

and conversion of MQ coherences are orientation dependent processes, a feature which opens up the possibility of imparting extra evolution phases to the spin coherences that do not relate to the second order effects, and hence may fail to refocus during the course of the experiment (Figure 8). For instance a sequence which efficiently transforms S_x^{MQ} into S_x^{1Q} but which at the same time generates an appreciable S_y^{1Q} component may be associated with a large $|\varepsilon|^2$ value, but will at the same time induce a net rotation in the $\{S_x^{1Q}, S_y^{1Q}\}$ space that prevents the full refocusing of anisotropies via the $MQ \rightarrow 1Q$ correlation. It is possible to associate the overall anisotropy of the excitation and conversion processes with the powder distribution of the ε phase factor: $\phi(\Omega) = \arctan[\varepsilon_y(\Omega)/\varepsilon_x(\Omega)]$. This parameter describes the relative phase with which the rf pulse sequence itself (as opposed to the actual internal spin interactions) transforms the equilibrium magnetization into observable x and y components via an intermediate MQ step. A narrow distribution of the $\phi(\Omega)$ values over the powdered sample is therefore another important goal to achieve for maximizing the sensitivity. It is also possible to decompose the various x and y pulse sequence coefficients into spherical coordinates and re-express this whole treatment in terms of $\{S_\alpha^{1Q}, S_\alpha^{MQ}\}_{\alpha=\pm}$ spin coherences. One would then state that an important characteristic of any given pulse sequence is not only the absolute efficiencies of its various processes, but also the relative efficiency with which it transforms the $S_z = 0$ magnetization first into separate $+m$ and $-m$ coherences, and subsequently each of these into observable magnetization of coherence order -1 . Considerations on the line shape distortions that may then arise in connection with the different efficiencies of the $0 \rightarrow \pm m \rightarrow -1$ coherence transfer pathways are further discussed below, as well as elsewhere (see **MQMAS Advances**).

3.2 Overview of MQMAS Pulse Sequences

As mentioned, the main actors in the MQMAS pulse sequence excitation and conversion processes are the rf and the first order quadrupole interactions. The former creates the various nonequilibrium states while the latter, even though absent during the evolution and acquisition periods, is in fact the coupling that enables the generation of MQ states. There are also other factors affecting the various stages of the pulse sequence including the spinning speed, which controls the temporal oscillations of the quadrupole coupling during the course of the rf pulses, as well as the shifts arising from the chemical shielding and second order quadrupolar interactions. Additional variables available in the design of the pulse sequences include the amplitudes, phases and frequencies of the various rf pulses involved in the MQ excitation and conversion, as well as the number of pulses involved in each stage. Figure 9 presents a number of strategies that have hitherto been proposed for the implementation the excitation and conversion steps of MQMAS acquisitions on spin-3/2.

Although simple, a sequence composed by two short pulses (Figure 9a) is capable of affording MQMAS spectra and provides insight into the general spin physics of more complex procedures. This experiment involves a short initial pulse which transforms the initial equilibrium polarization into high order MQ coherences, a free evolution period t_1 , and a second short pulse that converts the evolving MQ coherences into observable 1Q magnetization. Such pulse sequence was

Figure 8 Potential echo spoiling effects of pulses throughout an MQMAS sequence. Dashed lines correspond to the starting spin states, full lines illustrate the finishing states. In an ideal pulse sequence (a) the spin packets of different crystallites evolve under the effects of internal anisotropies and pulses are only responsible for the direct excitation and transfer of coherences among the subspaces. A complete reversal of the anisotropic evolution occurs, and hence magnetizations of all crystallites refocus along a common axis (assumed here to be the x -axis). In actual experiments (b) the orientation dependence of the excitation and conversion processes may induce net evolution phases which prevent a full reversal of anisotropies

Figure 9 Some of the pulse sequences proposed for the acquisition of 2D MQMAS spectra. (a) Basic two-pulse sequence implementing the excitation and conversion of the multiple-quantum coherences with short CW pulses. (b) Variant based on MQ coherence manipulations driven by adiabatic passages between $MQ \leftrightarrow 1Q$ states, with the initial MQ excitation being aided by a central transition 90° excitation pulse. (c) Sequence incorporating a fast-amplitude modulation (FAM) of the MQ conversion pulse. In general short CW, RIACT and FAM pulses (as well as other rf pulse modules, such as composite pulses or double-frequency-sweep pulses) can be combined in various forms to achieve a maximization of the MQMAS signal and optimization of the line shapes. Alternatives to the simple $MQ(t_1)$ - $1Q(t_2)$ scheme are shown on the right-hand column and include the introduction of a z -filter (d), whole echo detection during t_2 (e), and a split- t_1 scheme followed by a z -filter and Carr-Purcell-Meiboom-Gill acquisition. Staffs underneath each pulse sequence describe the corresponding coherence transfer pathways required for detecting the MQMAS echo and anti-echo signals (full and dashed lines, respectively). The actual coherence transfer pathway executed during the pulse sequence can be selected either by phase cycling^{20,75} or via the application of pulsed field gradients⁷⁶

initially proposed for performing double- and triple-quantum NMR spectroscopy on static powders and single crystals,^{49–51} and currently finds widest application in MQMAS experiments on half-integer quadrupolar nuclei. An exact analysis on the nature of this sequence requires propagating the evolution of the spins as a function of all the coupling parameters mentioned earlier (spin number S , transition order m , quadrupole coupling parameters C_Q , η_Q , shielding parameters $\nu_{\text{iso}}^{\text{CS}}$, $\nu_{\text{aniso}}^{\text{CS}}$, Larmor frequency ν_O , spinning rate ν_r , transverse rf nutation field ν_1). Such calculations have been carried out for a range of conditions;^{23,28,34,40} they are useful and eventually even necessary, yet sometimes some basic features of the experiment can also be gathered from simpler analytical treatments. One such analysis assumes only static first order quadrupolar and rf Hamiltonians:¹⁵

$$H_{\text{irr}} = C_Q \sqrt{\frac{1}{6}} R_{20}(\theta, \varphi) [3S_z^2 - S(S+1)] + \nu_1 S_x \quad (13)$$

Nuclear spins initially in a thermodynamic equilibrium state parallel to the z -axis will be excited by this irradiation to yield, among other states, the desired 3Q coherences. The origins of this MQ excitation process can be appreciated by diagonalizing H_{irr} , and describing the resulting Hamiltonian in terms of fictitious spin-1/2 operators.^{51,52} It can then be shown that for a spin $S = 3/2$ the result contains, among other components, a triple-quantum transverse excitation term proportional to S_x^{1-4} . This MQ excitation operator comes as a higher order rf effect mediated by the quadrupolar term, which excites the initial population into S_y^{1-4} coherences according to

$$S_z \xrightarrow{H_{\text{irr}} \tau_{\text{exc}}} 3 \sin \left(\frac{3}{8} \frac{\nu_1^3}{\nu_Q^2(\theta, \varphi)} \tau_{\text{exc}} \right) S_y^{1-4} \quad (14)$$

Note the unusual dependence of the nutation rate, as well as a factor of three magnifying the MQ coherence. The former derives from the higher order nature of this excitation, which scales the effective rf by a factor $(\nu_1/\nu_Q)^2$. The latter derives from the direct $S_z^{1-4} \rightarrow S_y^{1-4}$ process promoted by the S_x^{1-4} excitation term in H_{irr} . Although this prediction of a single nutation frequency for the buildup of single-crystallite triple-quantum coherences is just an approximation, it is quite a good one, mainly if the rf pulse is short enough to neglect other factors such as sample rotation, second order effects, and isotropic/anisotropic offsets. The nutation curves for a powdered sample can then be computed as a weighted superposition of single crystal nutation patterns for all possible (φ, θ) angles (Figure 10a). These theoretical predictions match well with MQMAS NMR experiments and predict that over a range of ν_1/ν_Q ratios, a growth in the MQ excitation occurs for increasing rf fields. This feature has led to the development of customized MQMAS probes capable of delivering intense pulses for short periods of time, reaching in favorable cases nutation rates in excess of 200 kHz. As for more conventional rf settings, one of the main reasons precluding the efficient excitation of MQ coherences with low nutation fields is the relatively long periods required for achieving the desired buildup. These then become comparable to the duration of the rotor period, and the MAS-driven averaging of $H_Q^{(1)}$ deprives the process from much of its effectiveness. Even under such conditions it has been observed

Figure 10 Triple-quantum excitation (a) and conversion (b) nutation behavior expected for a $S = 3/2$ nucleus subject to short CW pulses (sequence in Figure 9a), calculated for a static powdered sample as a function of different C_Q/ν_1 ratios: $C_Q/\nu_1 = 2$ (dotted lines), $C_Q/\nu_1 = 4$ (dashed lines), $C_Q/\nu_1 = 6$ (continuous lines). In all cases an axially symmetric quadrupole tensor with $C_Q = 400$ kHz was assumed; spins were assumed at thermal equilibrium for the excitation calculations, and at $S_x^{1-4} = S_y^{1-4} = 1$ for the $3Q \leftrightarrow 1Q$ conversion ones (adapted from Ref.¹⁵)

that the excitation of MQ coherences can still be carried out continuously through the course of several rotor periods, provided that the amplitudes of the rf nutation fields are set between multiples of the sample spinning speed.⁴⁷

A MQ excitation mechanism approach different from the one just discussed is the rotationally induced adiabatic coherence transfer (RIACT).²⁶ This effect exploits the fact that MAS will effectively null the quadrupolar frequency of a crystallite a number of times during the course of a rotor period, and that at these zero crossings a transverse rf field may redistribute the spin coherences among all eigenstates within the spin manifold.⁵³ Coherences that had been initially excited into transverse $\{S_i^{2-3}\}_{i=x,y}$ magnetizations of the central transition may end up during these zero crossings redistributed into higher $\{S_i^{1-4}\}_{i=x,y}$, giving rise to the desired MQ excitation. These experiments will therefore involve an initial central transition pulse, which can usually be made highly efficient for all crystallites in the sample, followed by a spin locking period during which the $1Q \rightarrow MQ$ transfer occurs (Figure 9b). In order to ensure that most crystallites in the sample undergo at least one zero crossing but avoid the occurrence of multiple crossings (which would transfer coherence back from $MQ \rightarrow 1Q$), the RIACT spin-lock excitation is usually kept within 1/4–1/3 of a rotor period.

Under optimal conditions of adiabatic passage, the transfer will be complete for all crystallites regardless of their individual quadrupolar frequencies and thus exhibit an improvement over the short-pulse approach in Figure 9(a).

Both short continuous wave (CW) as well as spin-locking pulses can be used as starting points for implementing the $MQ \rightarrow 1Q$ conversion process. Indeed it can be shown that such conversions involve simultaneous manipulations of the satellite $\pm 1/2 \leftrightarrow \pm 3/2$, amenable to both kinds of pulse sequences. Furthermore, similar theoretical approaches to those used in the excitation can be employed to design sequences that optimize the MQ to single-quantum conversion processes. These show that in the presence of large first and second order quadrupolar effects both strategies are actually challenged; the short CW one by the high rf fields that it requires for meaningful excitations of the satellite transitions, and RIACT by its marked orientation and offset dependencies. For instance, in the short pulse case it can be shown that in contrast to the MQ excitation case [equation (14)], the conversion process possesses no well-defined nutation frequency for the various crystallites. This in turn leads to a relatively poor conversion efficiency even for a single crystal orientation, as well as to one which rapidly decreases with increasing C_Q/ν_1 ratios. Still, even for powder samples, a maximum at $\nu_1/\tau_{\text{conv}} \approx 0.2$ cycles can be localized corresponding to a transient coherent superposition of the individual single crystal signals (Figure 10b).^{15,23} Furthermore, rotational resonance excitation conditions for rf nutation rates $\nu_1 \approx \nu_r$, $2\nu_r$ have again been observed for these process.⁴⁷ In many instances the RIACT approach performs a better conversion than its CW counterpart, opening the possibility of using mixed short-pulse/RIACT sequences that become less sensitive to the strength of quadrupolar couplings and therefore more quantitative than either option in Figure 9(a,b). Yet the actual fate of the spin-locked states will also depend on a competition between the strengths of the first order quadrupole coupling separating central from satellite transitions, the rf field recoupling these transitions, the spinning rate controlling the time that central and satellite transitions will stay in contact during the zero-crossings, and the various offsets involved. It is in fact illustrative to compare the predictions that the echo efficiency parameter ε introduced earlier yields for the two kinds of pulse sequences. For a typical case $S = 3/2$, the overall magnitudes of these coefficients are indeed larger for an optimized RIACT than for the short CW pulse sequence (Figure 11), yet the fact that they are also further spread out in their ϕ powder values is indicative of larger line shape distortions⁵⁴ and may prevent RIACT from achieving a more effective refocusing performance.

In addition to these sequences based on the implementation of $MQ \rightarrow 1Q$ conversions via the use of square CW rf pulses, a series of recent papers has focused on the application of shaped and variable-frequency pulses to MQMAS. A promising shaped-pulse proposition involves replacing the square conversion pulses by amplitude modulated ones.^{38,39,42,45} This can be achieved via an actual modulation of the pulses' envelop, or by applying fast 180° phase shifts to the rf that will effectively split the on-resonance pulse into symmetric off-resonance components. Either approach can be used to efficiently excite the outlying satellite transitions involved in the $3Q \rightarrow 1Q$ conversion step (Figure 9c). In spin-3/2 MQMAS experiments of simple model compounds, enhancement of over

Figure 11 Comparison between the powder values taken by the $\{\varepsilon_\alpha\}_{\alpha=x,y}$ values in short-pulse (a) and RIACT MQMAS pulse sequences (b). Each point represents a different crystallite in the sample distributed over a solid sphere; both plots were calculated for identical MAS conditions: $S = 3/2$, $\nu_r = 10$ kHz, $C_Q = 1$ kHz, $\nu_1 = 100$ kHz. Notice the overall larger magnitudes but also the spread of coefficients in the RIACT case (courtesy of A. Goldbourt and S. Vega, Weizmann Institute)

300% have recently been reported with this simple procedure. A closely related approach involves using double-frequency-swept chirp pulses, capable of enhancing the MQ conversion steps by sweeping through the off-resonance satellite transitions.^{36,43} Theory predicts that either of these approaches may not perform as well for $S \geq 5/2$ spin systems as for their $S = 3/2$ counterparts. Still it has been shown that improvements can be achieved in some of these cases using pulses possessing a different amplitude modulation;^{41,46} these approaches also appear promising for manipulating higher orders of MQ coherences.

Additional ways to improve the line shape and signal-to-noise in half-integer quadrupolar NMR in general have also been proposed; these are worth considering when implementing a low sensitivity experiment such as MQMAS. One of them takes advantage of the inhomogeneous nature of the anisotropies in MQMAS' direct dimension, to generate multiple 1Q signals from a single scan using a Carr–Purcell–Meiboom–Gill echo train during the acquisition period (Figure 9f).⁴⁴ Another involves transferring spin order from the satellite to the central spin transitions of a $S = 3/2$ prior to the beginning of the experiment, an approach that proves helpful when starting the spin excitation directly from central S_z^{2-3} magnetization as in the RIACT case.^{48,55}

Most of these developments in the pulse sequence focused on optimizing the MQMAS signal intensities in the presence of small off-resonance irradiation offsets. This is usually a very good approximation if alkali metals or light main group elements, possessing relatively small shielding contributions ($\leq 0.1\nu_1$). But for the case of heavier elements possessing much large magnitudes in their chemical shift scales, these offsets may severely interfere with the excitation of the MQ coherences. In some situations extreme shielding effects may prevent the acquisition of MQMAS signals altogether, even when dealing with sites possessing small quadrupole couplings. The effects of chemical shielding offsets can be compensated in part by manipulating the MQ coherences via the use of amplitude-modulated or composite pulses.³³ Still, even under these optimal conditions the overall MQMAS signal is usually poorer than that observed in the absence of large chemical or second order quadrupolar shifts.

Although more complete discussions on the optimization of these various MQMAS sequences can be found in the cited literature, it should be remembered that usually ‘optimal’ pulse values are just good initial starting points, susceptible to considerable improvement by even small variations in their timings. Before setting up a complete 2D MQMAS NMR acquisition it is therefore convenient to monitor the t_2 echo formation for a particular t_1 value, usually fixed at a small integer multiple of rotor periods in order to avoid the intense rotor-modulation imposed by spinning on MQMAS signals, and then vary the individual pulse width parameters around the suggested values until the strongest MQ signal has been detected. Only with these optimized values is it worth devoting the amount of spectrometer time that is required for the acquisition of a complete 2D MQMAS NMR spectrum.

4 FINE STRUCTURE OF THE MQMAS NMR LINE SHAPES

In addition to a successful refocusing of the interactions, retrieving quality half-integer quadrupolar line shapes by MQMAS demands dealing with a number of peculiarities related to the nature of this experiment. Most important among these is the presence of mixed-phase peak distortions. Mixed phase line shapes comprise one of the well-known limitations of 2D Fourier transform NMR, stemming from the indirect detection of one (or more) of the evolving frequencies.²⁰ Avoiding the dispersive artifacts that arise in these peaks requires some form of time-reversal involving either the formation of a spin-echo, the acquisition of separate echo/anti-echo or cosine/sine MQ-modulated signals (corresponding to different combinations of $+t_1$ and $-t_1$ evolutions), or the simultaneous acquisition of echo + anti-echo amplitude-modulated signals followed by their disentanglement via techniques such as time-proportional phase incrementation (TPPI) or off-resonance irradiation (discouraged for this experiment due to the reasons mentioned in the previous paragraph). Since MQMAS is actually an echo experiment, these mixed phase artifacts are not usually too severe. But when requiring highly-resolved or purely absorptive line shapes, the acquisition of echo and anti-echo signals with identical intensities for all crystallites is required. As mentioned earlier such acquisitions are in many instances hard or impossible to implement due to the different phase factors adopted by the ε parameter of the crystallites as a function of their orientation. Similar problems have been encountered in solution phase NMR, where it was shown they can be alleviated by introducing an intermediate step where coherences are momentarily stored along the z -axis and only then made into observable 1Q magnetizations. The resulting so-called z -filter approach (Figure 9d) ends up using a $0 \rightarrow \pm MQ(t_1) \rightarrow 0 \rightarrow -1(t_2)$ coherence transfer scheme, thereby requiring the addition of an extra pulse into the MQMAS sequence and sacrificing part of the signal.²⁴ On the other hand, the advantage of this z -filter lies in the fact that since efficiencies for $+MQ(t_1) \rightarrow 0 \rightarrow -1(t_2)$ and $-MQ(t_1) \rightarrow 0 \rightarrow -1(t_2)$ can now be made equal, purely absorptive 2D peaks result. Alternatively, mixed t_1 periods including both MQ and 1Q evolutions followed by acquisition of whole echoes over t_2 (Figure 9e,f) can be used to retrieve purely absorptive line shapes.^{29,56} Further details on the nature

Figure 12 Spinning sideband structure displayed by the ^{23}Na MQMAS NMR spectrum of Na_2SO_4 recorded at 4.7 T with sample spinning at $\nu_r = 6$ kHz. Data were acquired using a two-pulse sequence (Figure 9a) and subject to a shearing to yield a high resolution dimension; they should lead to a single centerband (cb) peak. Asterisks indicate spinning sidebands originating from modulations of the central transition anisotropies, shifted along ν_1 as a result of a shearing of the data. All remaining spinning sidebands, appearing mainly along the indirectly detected ν_1 axis, are artifacts peculiar to the excitation and conversion orientation dependencies of the MQMAS pulse sequence (adapted from Ref.⁵⁷)

of these distortions and on strategies for avoiding them are given in detail in (see **MQMAS Advances**).

Another line shape feature characterizing MQMAS NMR spectra is the occurrence of extensive spinning sidebands in the indirectly detected MQ frequency domain (Figure 12). These sidebands behave like their conventional spin-1/2 counterparts in that they are absorptive and appear at multiples of the rotor frequency with decreasing intensities as the spinning speed is increased; their origin, however, does not necessarily relate to the usual spinning-induced time modulation of chemical shift, dipolar or second order quadrupolar interactions. Indeed MQMAS spinning sidebands can span a significantly larger frequency range than those corresponding to the static magnitudes of these nuclear interactions, and are often a consequence of the orientation dependencies associated with the nutation pulses used for MQ excitation and MQ detection.^{57,58} A rigorous analysis of such problems requires introducing into the effects of the rf pulse involved in the MQMAS sequence, the explicit time-dependent oscillations of the first order quadrupolar frequencies during t_1 . Such an approach reveals that the rotational sideband intensities are mainly a function of e^2qQ/h and η_Q ; since analyses of the MQMAS frequency line shape can yield these internal coupling parameters, simulating these indirect-domain spinning sideband patterns often yields only redundant information. From this theoretical analysis it also follows that either orientation-independent excitation or conversion processes will be needed to remove the appearance of these artifacts; these goals have hitherto proved elusive to achieve.

Another source of MQMAS line shape distortions worth discussing are the nonsecular dipolar couplings that arise from other proximate quadrupole nuclei I . Such couplings have been extensively documented in ^{13}C MAS NMR, and are known to arise due to the quadrupole-induced tilting of I 's

nuclear spin quantization axes.⁵⁹ These effects also show up in MQMAS NMR,^{60–63} as neither the spin nor the spatial manipulations involved in this experiment can take care of their averaging. Such residual couplings can be of either homo- or heteronuclear nature, and their effects are usually smaller as magnetic fields increase. Of the various coupling scenarios, the simplest to describe is the high field heteronuclear one;⁶² MQMAS line shapes here are made up of $2I + 1$ components whose centers of mass are placed at offsets

$$\nu_{\text{iso}}(m_I) = \frac{[|C_S^4(m)| + 2mC_S^4(\frac{1}{2})]}{C_S^4(\frac{1}{2}) + |C_S^4(m)|} \times \{[3m_I^2 - I(I+1)]\Delta + m_I J\} \quad (15a)$$

where

$$\Delta = \frac{3}{20} \frac{D_{zz}^{\text{eff}} C_Q^I}{\nu_O^I} (3 \cos^2 b - 1 + \eta_Q^I \sin^2 b \cos 2a) \quad (15b)$$

is a parameter depending on I 's quadrupolar and Larmor as well as on I – S 's dipolar coupling. As can be gathered from these expressions, such couplings are usually magnified by the MQMAS experiments, leading to complex multiplets that may impair the method's resolution (Figure 13) but which can also convey valuable coupling information.

Before concluding, it is worth dwelling on other issues affecting line shape resolution. When dealing with heteronuclear couplings to abundant spin-1/2 nuclei, such as in organic systems, the highest resolution proves hard to achieve by

simple MAS averaging. This can be aided via heteronuclear decoupling, yet the magnification brought about by dealing with MQ evolutions may demand in these cases the use of efficient decoupling schemes for maximizing resolution.^{64,65} Considerable resolution limitations can also arise in homonuclear systems from a different source: the flip-flop terms present in such dipole–dipole couplings, which do not commute with the longitudinal terms in the quadrupolar Hamiltonians.^{74,78} If such homonuclear effects are present and strong, a fast-decaying MQMAS echo showing little resolution enhancement when compared to conventional MAS line shapes may result. Furthermore these effects may result in broadenings which decay only slowly or sometimes even increase with spinning speeds, at least within the range of normally used ν_r values.⁶⁶ Finally, it is also worth noting that a dependence of the spectral resolution has also been noted on the order m used in MQMAS experiments:^{30,67,68} for $S \geq 5/2$ nuclei, a higher resolution tends to be achieved for the maximum MQ order available in the manifold. This can be rationalized by the different m -dependencies exhibited by the isotropic chemical and quadrupolar shifts, transforming as $2m$ and $C_O^S(m)$, respectively. The largest values of these weighting coefficients are usually found for the $m_I = S$ condition; a $-S \rightarrow -1$ coherence transfer pathway is then required for achieving a refocusing of anisotropies and this choice further reinforces the resolving power of the various isotropic contributions along the high resolution domain. Even further refinements on this approach can be proposed if one allows the pulse sequence to subsequently encode several MQ orders throughout the course of the indirect t_1 evolution;⁶⁹ it then becomes feasible to devise acquisition schemes that maximize resolution for almost arbitrary shift values, even if at the expense of substantial sacrifices in signal-to-noise.

5 OUTLOOK

This review discussed some of the basic features of 2D MQMAS NMR as they apply to the acquisition of high resolution spectra from half-integer quadrupolar nuclei. As an analytical tool for resolving inequivalent chemical sites, the technique appears to be experimentally simple and applicable to a large number of elements. It can be used to distinguish isotropic chemical from isotropic quadrupolar shifts, as well as to pinpoint the quadrupolar coupling parameters $e^2 Qq/h$ and η_Q of individual chemical sites. Remarkable also is the extensive spin-physics that have been triggered by this experiment, reawakening a mostly dormant interest in the field of MQ quadrupolar NMR in solids. Due to space constraints many of the underlying principles developed in connection with the manipulation of MQ coherences throughout this experiment have only been briefly discussed. As mentioned, this material is covered in further detail in the original literature, in a number of recent reviews^{70–73} as well as in accompanying articles in this Encyclopedia.

As the number of MQMAS applications continues to grow, a number of challenges to be resolved are also becoming increasingly clear. Some of these are of a technical nature, and involve issues such as employing MQMAS data for quantifying the abundance of chemical sites and/or for improving the signal-to-noise ratio of the experiment. Indeed, although significant advances have been made in these areas important

Figure 13 Progressive broadening introduced into the isotropic dimension of MQMAS line shapes (a) by the residual dipolar (b) and J (c) couplings between a spin S and a quadrupolar heteronucleus. Tensors were in all cases assumed axially symmetric and coincident, and the frequency scales refer to an isotropic shift $\delta_S = 0$ kHz. Spectra on the left assumed 3QMAS NMR on an $S = 3/2$ ($e^2 q Q/h = 2$ MHz, $\nu_O = 64.4$ MHz) coupled to an $I = 1$ ($e^2 q Q/h = 3$ MHz, $\nu_O = 14.5$ MHz) with a $D_{zz}^{\text{eff}} = 1.7$ kHz; the center and right columns describe the 3QMAS and 5QMAS spectra of an $S = 5/2$ ($e^2 q Q/h = 3$ MHz, $\nu_O = 52$ MHz) coupled to an $I = 3/2$ ($e^2 q Q/h = 12$ MHz, $\nu_O = 20$ MHz). J couplings throughout row (c) were set at 100 Hz (adapted from Ref.⁶²)

obstacles to overcome still remain, for instance when it comes to observing low- γ nuclei, to characterizing systems affected by substantial chemical shieldings, or to unlocking the potential of 5Q and 7Q MAS spectroscopies towards improving the spectral resolution. Yet it is also clear that even in its present form MQMAS can be a significant aid in enhancing the NMR information afforded by a variety of chemical systems.

A second and perhaps longer-range type of problem triggered by MQMAS, stems from the nature of the method as a mean rather than as an end. Indeed, once inequivalent resonances appear resolved by MQMAS, the real problem of analyzing the meaning of these NMR data begins. For many of the spin isotopes being analyzed by MQMAS this challenge is currently hard to overcome, as the assignment of quadrupolar and shielding parameters to individual chemical sites remains for the most part uncharted. Quantum chemical calculations of NMR coupling parameters are a potentially good starting point for establishing such correlations, yet in many instances their usefulness is compromised by the heavy-element and multi-electronic nature of the isotopes being analyzed. An alternative to this assignment approach relies on employing the X-ray structures available for model systems, in combination with spectral editing techniques based on the dipolar dephasing imposed by nearby nuclei, in order to empirically correlate MQMAS-resolved coupling parameters with specific coordination and bonding motifs. This in turn highlights the need to further develop homo- and heteronuclear recoupling techniques on quadrupole nuclei, and for making these recoupling protocols integral parts of the MQMAS methodology. Driven by this need, it is reasonable to expect this research area to become within the near future as active a topic of investigation as it has become for its spin-1/2 counterparts.

1 REFOCUSING AND DEPHASING

Rotational echo double resonance (REDOR) NMR is a new analytical spectroscopic technique for solids spinning at the magic angle which has been developed during the last 6 years.¹ REDOR provides a direct measure of heteronuclear dipolar coupling between isolated pairs of labeled nuclei. In a solid with a ^{13}C – ^{15}N labeled pair, for example, the ^{13}C rotational echoes that form each rotor period following a ^1H – ^{13}C cross polarization transfer can be prevented from reaching full intensity by insertion of a ^{15}N π pulse each half rotor period (Figure 1). The ^{15}N pulse in the middle of the evolution period is replaced by a ^{13}C pulse so that isotropic carbon chemical shifts are in phase at the beginning of data acquisition. The REDOR difference (the difference between a ^{13}C NMR spectrum obtained under these conditions and one obtained with no ^{15}N π pulses) has a strong dependence on the ^{13}C – ^{15}N dipolar coupling and hence the ^{13}C – ^{15}N internuclear distance.² REDOR is described as double resonance even though three radiofrequencies (typically ^1H , ^{13}C , and ^{15}N) are used because the protons are removed from the important evolution part of the experiment by resonant decoupling. The dephasing of magnetization in REDOR arises from a local dipolar ^{13}C – ^{15}N field gradient and involves no polarization transfer. REDOR has no dependence on ^{13}C or ^{15}N chemical shift tensors and does not require resolution of a ^{13}C – ^{15}N coupling in the chemical shift dimension.²

The evolution of observable S -spin magnetization for a single crystallite on resonance under magic angle spinning and an I – S dipolar coupling is shown in Figure 2 (left). Each dot represents the result of evolution for an equal fraction of a rotor period, with a minor homogeneous decay superimposed for display purposes. At the beginning of the rotor cycle, the magnetization is the observable, $\langle \hat{S}_x \rangle$. Under sample rotation and I – S dipolar coupling, the observable magnetization is transformed into nonobservable bilinear coherence, $\langle \hat{I}_z \hat{S}_y \rangle$, and then back into $\langle \hat{S}_x \rangle$. By the end of the rotor cycle the full observable magnetization has been recovered. For a collection of crystallites in a powder, individual phase accumulations (the product of resonance frequency and time) vary in size and sign depending on crystallite orientation in the magnetic

Figure 1 Pulse sequence for a version of REDOR ^{13}C NMR. Two equally spaced, ^{15}N 180° pulses per rotor period result in the dephasing of transverse carbon magnetization produced by a cross-polarization (CP) transfer from dipolar-coupled protons. Carbon–nitrogen dipolar coupling determines the extent of dephasing. A ^{13}C 180° pulse replaces the ^{15}N pulse in the middle of the dephasing period and refocuses isotropic ^{13}C chemical shift differences at the beginning of data acquisition. After the CP transfer, resonant decoupling removes the protons from the experiment. The illustration is for four rotor cycles

field. This causes phase interference during the rotor cycle and an apparent decay of the observable signal for the powder. Nevertheless, because the magnetization from each crystallite refocuses completely, the dephasing for the powder is also refocused into a full rotational echo at the end of the rotor cycle.

However, even for a single crystallite, the refocusing is incomplete in the presence of dephasing I -spin π pulses (Figure 2, right). Evolution for the crystallite is identical to that shown at the left of the figure between times ‘1’ and ‘2’. The I -spin inverting π pulse, which ends at time ‘3’, changes the sign of $\langle \hat{I}_z \hat{S}_y \rangle$. This process is repeated under the second I -spin π pulse which ends at time ‘5’. At the end of the rotor cycle (time ‘6’), the transformation of bilinear coherence created during the rotor cycle into observable magnetization is incomplete. For a powder, a rotational echo of diminished intensity is observed. The extent of the diminution depends on the I – S coupling. The diminution is maximum for two dephasing pulses and is independent of their exact placement so long as the pulse spacing is one-half of the rotor period.²

2 REDOR DEPHASING FOR RECRYSTALLIZED LABELED ALANINES

The results of a REDOR experiment performed using the pulse sequence of Figure 1 on an equimolar, recrystallized mixture of L-[2- ^{13}C , ^{15}N]alanine and L-[1- ^{13}C]alanine are shown in Figure 3.³ The full echo ^{13}C NMR spectrum (S_0) after two rotor cycles with no dephasing is at the bottom of the Figure, and the REDOR difference ($\Delta S = S_0 - S$, where S is the spectrum with dephasing) as a function of the number of rotor cycles, is shown at the top of the Figure. The 900 Hz intramolecular ^{13}C – ^{15}N coupling results in a sizeable ΔS for the methine carbon atom after only two rotor cycles; this ΔS reaches a maximum after four rotor cycles, and then oscillates in amplitude. The average 100 Hz intermolecular coupling produces a small carboxyl carbon atom ΔS after two rotor cycles, which increases monotonically with dephasing time.

Figure 2 Schematic diagram of the evolution of the IS density matrix for a single crystal under magic angle spinning and $I-S$ dipolar coupling during a REDOR pulse sequence with no dephasing pulses (left) and with dephasing pulses (right)

Figure 3 The 50.3-MHz REDOR ^{13}C NMR spectra of an equimolar, recrystallized mixture of L-[2- ^{13}C , ^{15}N]alanine and L-[1- ^{13}C]alanine, as a function of the number of rotor cycles. A full echo spectrum (S_0) after two rotor cycles is shown at the bottom of the Figure and REDOR difference spectra (ΔS) at the top. Magic angle spinning was at 2702 Hz

The $\Delta S/S_0$ ratios for both carbon atoms have the same dependence on the dimensionless parameter, λ_D (Figure 4, solid circles and squares). The theoretical dependence (Figure 4, solid line) was calculated by performing an isotropic powder average over the dephasing for individual crystallites (Figure 2, right). Thus, the angular dependence of the dipolar interaction is suppressed. The resulting universal dephasing behavior needs to be calculated only once for all heteronuclear spin-1/2 pairs. (REDOR applications also include quadrupolar nuclei like ^2H , with either direct observation of deuterium or indirect observation through REDOR dephasing. Calculation of the theoretical $\Delta S/S_0$ behavior is slightly more complicated.)⁴

Figure 4 Observed dependence of $\Delta S/S_0$ on the universal parameter, λ_D , for the ^{13}C - ^{15}N double-labeled alanine mixture of Figure 3. (N is the number of rotor cycles with dephasing, D is the dipolar coupling constant, and T_r is the rotor period)

A few experimental values of $\Delta S/S_0$ determine λ_D , which then establishes D since the total dephasing time (the product of the number of rotor cycles of dephasing and the rotor period) is known. Because $D = \gamma_I \gamma_S \hbar / 2\pi r^3$, the observed dephasing can be translated into an internuclear distance directly. If $\Delta S/S_0$ and hence D are known experimentally to 10%, the distance is known with 2% accuracy. Weak dipolar couplings associated with large internuclear distances can be effectively amplified in REDOR by simply allowing the rotor to go around. The only practical problem is holding the echo train together. This depends on the technical difficulty of completely decoupling the protons, which may require low temperatures to suppress kHz regime molecular motions.⁵ Translating dipolar couplings into distances in the presence of large-amplitude motions involves specifying a model for the motion.⁶

3 LONG-RANGE COUPLINGS AND THE NATURAL-ABUNDANCE BACKGROUND

In the early applications of REDOR to C–N distance determinations in peptides, relatively few dephasing pulses were used so that sometimes large natural-abundance corrections were necessary.⁷ More recently, increased dephasing has been possible as a result of the development of phase routing schemes⁸ (Figure 5) that eliminate the dependence of REDOR determinations on frequency offsets and pulse imperfections.⁹

For example, the ^{13}C signal for the label in the nine-residue emerimicin fragment, Ac-Phe-[1- ^{13}C]MeA₂-MeA-MeA-Val-[^{15}N]Gly₆-Leu-MeA-MeA-O-Bzl, where Ac = acetyl, Phe = phenylalanine, MeA = methylalanine, Val = valine, Gly = glycine, Leu = leucine, Bzl = benzyl is not resolved from that of natural-abundance peptide carbonyl carbon atoms, which make a constant 7.7% contribution to the full echo signal, S_0 . This correction can either be measured in a separate experiment on a natural-abundance sample, or calculated from the known structure.¹⁰ In addition, the natural-abundance ^{13}C carbonyls of Val₅ and Gly₆ are, respectively, one and two bonds away from the ^{15}N label and so will make a contribution to ΔS that reaches a maximum value of 2% by about $N_c = 16$. The other natural-abundance carbonyl ^{13}C atoms are all farther away from the ^{15}N label than is the

Figure 5 REDOR pulse sequence with dephasing π pulses on both the nitrogen and carbon channels. The pulses are applied using an xy -8 phase cycling scheme to eliminate offset effects and pulse imperfections. Signal acquisition begins two rotor cycles after the completion of a full $8N$ rotor cycles of dephasing. CP = cross polarization. Acq = acquisition

Figure 6 Observed dependence of $\Delta S/S_0$ on the universal parameter, λ_D , for a ^{13}C – ^{15}N double-labeled fragment of emerimicin. The pulse sequence of Figure 5 was used. The experimental results (solid circles) are in agreement with calculation (solid line) assuming a ^{13}C – ^{15}N dipolar coupling of 40 Hz corresponding to a C–N distance of $4.1 \pm 0.1 \text{ \AA}$. The natural-abundance correction to $\Delta S/S_0$ at $N_c = 8$ is 50% and at $N_c = 100$ is 4%

carbonyl label at MeA₂. Thus, for $N_c > 32$, the observed ΔS is dominated by the coupling of the ^{15}N – ^{13}C labels and additional natural-abundance corrections are unimportant. By $N_c = 96$, $\Delta S/S_0$ is greater than 0.7 (Figure 6), consistent with a D value of 40 Hz, corresponding to a C–N distance of $4.2 \pm 0.1 \text{ \AA}$. The distance by X-ray analysis¹¹ is $4.16 \text{ \AA}$. The natural-abundance correction to D is less than 2 Hz when $N_c = 96$, which means that less than a 0.05- $\text{\AA}$ correction for the C–N distance is required. The agreement between X-ray and REDOR determinations of the [1- ^{13}C]MeA₂–[^{15}N]Gly₆ distance for this calibration sample for $N_c = 8$ to $N_c = 112$

Figure 7 Pulse sequence for TEDOR I – S NMR. Following a cross-polarization (CP) transfer from abundant protons to generate initial I -spin magnetization, the effect of the protons is removed by resonant decoupling. The π pulses are shown separated by one-half rotor periods. The coherence transfer is achieved by simultaneous $\pi/2$ pulses in the middle of the evolution period. The solid circles represent observable magnetization

Figure 11 TEDOR–REDOR ^{13}C NMR spectra of a ^{19}F , ^{13}C , ^{15}N -labeled emerimicin (see Figure 6). The TEDOR spectrum (bottom) was obtained using an N–C coherence transfer as illustrated in Figure 7. The TEDOR–REDOR difference spectrum (the difference between TEDOR spectra with and without dephasing REDOR pulses) is shown at the top of the Figure. This spectrum was obtained by ^{19}F dephasing of the ^{15}N -TEDOR-selected ^{13}C magnetization over 40 rotor cycles

Background corrections for ^{13}C -observe ^{15}N -dephase REDOR are relatively simple to calculate because the ^{15}N natural abundance is low and γ_{N} is small. A measured value involves a separate sample with no ^{15}N label. The minor, observed $\Delta S/S_0$ for the single-labeled sample is then usually just subtracted from that for the double-labeled sample.³ The correction is more involved for ^{13}C - ^{31}P and ^{13}C - ^{19}F pairs. For example, a ^{19}F -observe ^{13}C -dephase REDOR experiment designed to measure the dipolar coupling for a labeled ^{19}F - ^{13}C pair separated by 10 Å must take into account the sizeable number of natural-abundance ^{13}C atoms within dephasing range of the ^{19}F . One way¹³ to interpret the observed $\Delta S/S_0$ is to generate a model lattice with 1% randomly distributed ^{13}C . If all ^{13}C - ^{13}C coupling is ignored, the ^{19}F -observed, ^{13}C -dephase REDOR ΔS can be interpreted in terms of a collection of independent, $^{19}\text{F}(\text{label})$ - $^{13}\text{C}(\text{label})$ - $^{13}\text{C}(\text{natural abundance})$, three-spin clusters, whose dipolar-tensor orientations are known from the lattice parameters.

4 COHERENCE TRANSFER AND SELECTIVITY

Sometimes a natural-abundance background cannot be measured or calculated easily. In this situation, the dipolar-coupled spins can be selected from among the background of uncoupled spins by a coherence transfer from one spin of

the heteronuclear pair to the other. The pulse sequence for this selection is shown in Figure 7. Transverse magnetization is first established in the I -spin system by a cross-polarization transfer from abundant protons. The dephasing of I -spin magnetization by dipolar-coupled S spins through rotor-synchronized S -spin π pulses leads to a bilinear coherence (Figure 8, left) that is transferred by an I, S pair of $\pi/2$ pulses (Figure 8, shaded arrow). These pulses occur together at the completion of a rotor cycle (Figure 7) and interchange the indices of the bilinear coherence. Finally, the transferred bilinear coherence is transformed into observable S -spin transverse magnetization by rotor-synchronized I -spin π pulses (Figure 8, right). The entire procedure is called transferred echo double resonance (TEDOR).¹⁴ TEDOR is a rotor-synchronized solid state experiment which is based on some of the same coherence transfer principles as the INEPT solution state experiment.

The results of a TEDOR experiment using the pulse sequence of Figure 7 performed on the mixed double-labeled alanine sample discussed above are shown in Figure 9. Proton polarization is first transferred to nitrogen atoms. Then three rotor cycles are used to create bilinear ^{15}N - ^{13}C coherence, and three more rotor cycles to produce observable methine carbon atom magnetization following the coherence transfer. The TEDOR theoretical transfer efficiency¹⁴ is 50% compared with the observed 35% (Figure 9). Because TEDOR is not a difference experiment, TEDOR has the same theoretical sensitivity as REDOR. No sizeable carboxyl

Figure 12 Two schemes for REDOR. (Left) Acquisition of a time domain signal follows evolution during which dephasing pulses diminish observable magnetization and create nonobservable I - S bilinear coherence. This scheme is suitable for multiline spectra and a separate $\Delta S/S_0$ is measured for each line in the spectrum. The dependence on λ_D is determined by varying the number of rotor cycles. (Right) Synchronous detection of a time domain signal during evolution is suitable for a single-line spectrum. The observed S/S_0 is $1 - (\Delta S/S_0)$. AQ = acquisition; SAQ = synchronous acquisition

carbon magnetization is observed in Figure 9 because the short evolution time was insufficient for the weak intermolecular ^{15}N – ^{13}C coupling to create significant bilinear coherence. If there had been a collection of nitrogen atoms all with comparable strong, couplings to carbon atoms, the TEDOR coherence transfer could still have been made selective by alternating the sign of the starting nitrogen magnetization for just one type of ^{15}N by DANTE inversion of the selected nitrogen atom signal every other scan.¹⁵ The sign of the transferred bilinear coherence would then alternate, as would that of the observed carbon atom magnetization corresponding to the selected ^{15}N – ^{13}C coupling. Data routing could then discriminate between carbon signals.

5 COMBINATION EXPERIMENTS AND SYNCHRONOUS DETECTION

TEDOR can be used alone or in combination to make highly selective TEDOR–TEDOR and TEDOR–REDOR experiments.¹⁶ The pulse sequence for the latter is illustrated in Figure 10. A TEDOR sequence is tailored to select the carbonyl carbon atom signal of residue 4 of a ^{19}F , ^{13}C , ^{15}N triple-labeled emerimicin fragment (Figure 11). The ^{15}N – ^{13}C selected magnetization is then dephased by REDOR ^{19}F π pulses resulting in the determination of a selected 8-Å C–F distance. This combination experiment involves four radiofrequencies in the same sequence which is possible using transmission-line probe technology.¹⁷ The tuning elements in these probes are outside the magnet in a large, shielded box with isolation of all radiofrequencies, making high power on four channels practical.¹⁸

The observed signal in the TEDOR–REDOR experiment can be detected either as part of a two-dimensional experiment in which full S and S_0 spectra are obtained by normal

Figure 13 Simulation of X-spin REDOR dephasing of I – S TEDOR-selected S -spin magnetization (solid line). The simulation assumed an I – S coherence transfer after two rotor cycles of dephasing, followed by two rotor cycles of transformation of coherence into observable S -spin magnetization (see Figure 7). For $S/S_0 > 0.5$, the simulation is almost independent of orientation of I – S and S – X dipolar tensors (results not shown) and closely matches that for a full isotropic powder (dotted line). All simulations were performed assuming that the I – S coupling was 1.2 kHz, the S – X coupling was 100 Hz, and the magic angle spinning was 5 kHz

acquisition starting with a rotor cycle (Figure 12, left), or synchronously with one sampling per rotor cycle (Figure 12, right). The former is used for complicated spectra with more than one resonance even after selection by TEDOR. The latter is used for the simple, one-line spectra that usually result from a TEDOR preparation. Synchronous detection² has the sensitivity advantage of generating the entire REDOR dephasing pattern in real time. The dipolar evolution dimension can be mapped by variation of the number of rotor cycles,¹ or variation of the position of the dephasing pulse within the rotor period.² The latter has a constant total dipolar evolution time which eliminates the echo-train lifetime from the analysis. In both of these two-dimensional methods, spins which contribute to the S -spin signal but have no I – S coupling (a common situation for a natural-abundance background) do not interfere with the determination of the I – S interaction.¹⁶ Such spins produce a constant offset in the dipolar time domain and so a zero-frequency spike in the dipolar frequency domain. The I – S coupling is determined by the width of the dipolar spectrum.²

Even an efficient TEDOR transfer does not result in observable magnetization associated with an isotropic powder. Thus, some crystallite orientations are discriminated against depending on the orientation of the IS and SX dipolar tensors in an I – S – X three-spin TEDOR–REDOR experiment. Nevertheless, following an efficient I – S TEDOR transfer, the *initial* S -observe, X -dephase REDOR behavior depends only on the size of the dipolar tensors and not on their orientation (Figure 13). Thus, interpretation of the 20% dephasing (Figure 14) in a TEDOR–REDOR experiment on the triple-labeled peptide of Figure 11 does not require knowledge of ^{15}N – ^{13}C – ^{19}F geometry in order to extract a C–F distance.¹⁶ This will be the situation for most long-range distance determinations in general, simply because little dephasing is observed and determination of the dipolar coupling is based on the initial S/S_0 behavior. However, for systems with stronger couplings, Fourier transforms of the TEDOR–REDOR dipolar evolution offer the opportunity to establish geometry by comparisons with theoretical dipolar lineshapes (Figure 15).

Figure 14 Synchronously sampled time domain ^{13}C signal of a ^{19}F , ^{15}N , ^{13}C -triple-labeled emerimicin diluted by natural-abundance peptide. The ^{15}N TEDOR-selected ^{13}C signal is sampled once each rotor period either with (S) or without (S_0) ^{19}F dephasing pulses. Magic angle spinning was at 5 kHz

Figure 15 Dipolar spectra obtained by Fourier transforms of time domain simulations performed as described in the caption to Figure 13. The widths of both dipolar spectra are determined by the 100-Hz $S-X$ coupling. Details of the lineshape are determined by orientation of $I-S$ and $S-X$ dipolar tensors

1 INTRODUCTION

Spin diffusion is a phenomenon in which spin information, or more specifically the spin magnetization, at one location of a substance is transported to other locations. In solids, where the translations of the spin-bearing atoms are highly restricted, the transport of spin information is mediated by spin–spin interactions. In the following, this transport phenomenon and its effects on NMR will be described. Historically, spin diffusion was considered a nuisance, because it tends to average out useful spin information that reflects the spatial heterogeneity of a solid. As will be described below, with an understanding of spin diffusion and appropriate NMR pulse sequences, one can actually extract spatial information about disordered solids such as polymers by following how the local magnetization is transported by spin diffusion.

Consider an isolated pair of identical spins $\frac{1}{2}$, I_1 and I_2 , in a strong external magnetic field. They are coupled to each other by an exchange interaction $\lambda \hat{I}_1 \cdot \hat{I}_2$. If the system is initially in the spin state $|\uparrow \downarrow\rangle$, the spins will evolve under the influence of the exchange interaction to the $|\downarrow \uparrow\rangle$ state in which there are opposite flips in the ‘directions’ of the two spins. The total wavefunction of the system can be expressed as

$$\varphi(t) = c_1(t) |\uparrow \downarrow\rangle + c_2(t) |\downarrow \uparrow\rangle \quad (1)$$

By solving the time-dependent Schrödinger equation, the probability that the system remains in $|\uparrow \downarrow\rangle$ is

$$|c_1(t)|^2 = \cos^2[(\lambda/\hbar)t] \quad (2)$$

and the probability that it evolves to $|\downarrow \uparrow\rangle$ is

$$|c_2(t)|^2 = 1 - \cos^2[(\lambda/\hbar)t] \quad (3)$$

Therefore, the exchange interaction leads to a cyclic transfer of spin information, which, in this case, is the magnetization of spin I_1 , represented by $|c_1(t)|^2 - |c_2(t)|^2$, from spin I_1 to spin I_2 , and then back to spin I_1 again, with a frequency of $\lambda/\hbar$.

In solids, nuclear spins like ^1H are strongly coupled by dipole–dipole interactions, the secular part of which has the form

$$\hat{\mathcal{H}}_d^0 = \frac{1}{4} \sum_i \sum_j \frac{(3 \cos^2 \theta_{ij} - 1) \hbar^2 \gamma^2}{r_{ij}^3} (\hat{I}_i \cdot \hat{I}_j - 3 \hat{I}_{iz} \hat{I}_{jz}) \quad (4)$$

where θ_{ij} is the angle between the direction of the external magnetic field and the vector joining the spin I_i at location $\mathbf{r}_i$ and the spin I_j at $\mathbf{r}_j$, and $\mathbf{r}_{ij} = |\mathbf{r}_i - \mathbf{r}_j|$. The exchange term $\hat{I}_i \cdot \hat{I}_j$ in equation (4) allows the exchange of magnetization between two coupled spins I_i and I_j . Because of the r_{ij}^{-3} dependence, the interaction can be restricted to nearest-neighbor spins. If the spins I_1 and I_2 mentioned earlier are a part of the solid and interact with many other spins I_i of the same kind, it becomes very likely that before the magnetization from spin I_2 returns to the spin I_1 , it will spread to other spins coupled to spin I_2 . This transfer of magnetization will continue to spins at farther distances from spin I_1 in a manner very similar to that of the random walk. Hence the term ‘spin diffusion’ was coined.^{1,2}

The spin diffusion equation can be formally derived from the dipole–dipole Hamiltonian in equation (4) using linearized projection operator techniques.³ However, it is much easier to understand in terms of the rate equation for the local magnetization $m(\mathbf{r}_i, t)$, which is defined as the thermal average of $\hat{I}_{iz}$ at time t :

$$\frac{\partial m(\mathbf{r}_i, t)}{\partial t} = \sum_j' W(\mathbf{r}_i, \mathbf{r}_j) [m(\mathbf{r}_j, t) - m(\mathbf{r}_i, t)] \quad (5)$$

This equation is an expression of linear response theory stating that the rate of change of the local magnetization at site $\mathbf{r}_i$ has a linear (i.e., first-order) dependence on the differences in the local magnetization between site $\mathbf{r}_i$ and its nearest-neighbor sites $\mathbf{r}_j$. $W(\mathbf{r}_i, \mathbf{r}_j)$ is the rate of the spin flip–flop induced by the dipole–dipole interaction between spins I_i and I_j , and is of the order of the spin–spin relaxation rate $(T_2)^{-1}$. The prime on the summation above indicates that the summation over j is restricted to nearest neighbors of the spin I_i . In the simple case where the nuclear spins are arranged in a cubic array, the summation along the x axis can be expressed as

$$a^2 W(\mathbf{r}_i, \mathbf{r}_i + a\mathbf{i}) \frac{\left(\frac{m(\mathbf{r}_i + a\mathbf{i}, t) - m(\mathbf{r}_i, t)}{a} \right) - \left(\frac{m(\mathbf{r}_i, t) - m(\mathbf{r}_i - a\mathbf{i}, t)}{a} \right)}{a} \quad (6)$$

where $\mathbf{i}$ is the unit vector along the x axis and a is the lattice constant. In the continuum limit, this reduces to

$$a^2 W(\mathbf{r}, \mathbf{r} + a\mathbf{i}) \frac{\partial^2 m(\mathbf{r}, t)}{\partial x^2} \quad (7)$$

Similar expressions can be obtained for the sums along the y and z directions. Neglecting the anisotropy of $W(\mathbf{r}, \mathbf{r} + a\mathbf{i})$ or replacing it with W , the average over the three directions, the rate equation becomes the diffusion equation

$$\frac{\partial m(\mathbf{r}, t)}{\partial t} = D \nabla^2 m(\mathbf{r}, t), \quad \text{with } D = a^2 W \quad (8)$$

Because the nonsecular part of the dipole–dipole interaction as well as other magnetic interactions that we have not considered can lead to spin–lattice relaxation of the nuclear magnetization, one should also include a relaxation term $-m(\mathbf{r}, t)/T_1(\mathbf{r})$ on the right-hand side of the spin diffusion equation when the spin relaxation rate is comparable to the diffusion rate.

Using the Fermi golden rule, the spin flip rate W can be expressed as

$$W \approx |\hat{H}_d^0|^2 f(\omega_i - \omega_j) \quad (9)$$

where ω_i and ω_j are the Larmor frequencies of the spins I_i and I_j , and $f(\omega)$ is the lineshape function of the spin pair due to

the action of all the other spins. It has a width of order T_2^{-1} and decays rapidly to zero with increasing ω . The difference in the Larmor frequencies ($\omega_i - \omega_j$) represents the amount of energy required to flip the two spins in opposite directions. The implication of equation (9) is that the rate of the spin flip is fastest; thus, the spin diffusion is most efficient when the spins have the same Larmor frequency, i.e., when the process is energy-conserving. If the difference in the Larmor frequencies is much larger than T_2^{-1} then the spin flip stops and the spin diffusion is quenched.

Equation (8) holds not only in the laboratory frame but also in the rotating frame, provided that the spin locking field is much larger than the dipolar interactions. For simplicity, we shall not distinguish between spin diffusion in these two frames unless the circumstance requires it and we shall adopt the notation T_L for the spin-lattice relaxation time in either frame.

Spin diffusion plays an important role in the understanding of spin-lattice relaxation phenomena in solids when spin relaxation can occur mainly at few isolated locations. For instance, at very low temperatures, spin relaxation in polymers with long molecular chains takes place mainly at the end groups, where motions are still possible. Paramagnetic impurities in crystalline materials also act as relaxation centers for the nuclear spins because of the rapid fluctuations of the electronic spin moments. The relaxation of the total magnetization

$$M(t) = \int_V m(\mathbf{r}, t) d^3r \quad (10)$$

where V is the sample volume, depends on both the relaxation rate at these centers and the rate at which the local magnetization is transported to these centers by spin diffusion.

The question of how well spin diffusion can be utilized to extract information about a system depends largely on one's ability to solve the diffusion equation according to appropriate sets of initial and boundary conditions. The methods of solving the spin diffusion equation are very similar to those used in heat conduction, and there are a number of excellent texts^{4,5} treating the latter in great detail. There is one fundamental fact about the diffusion process that should be borne in mind, namely, spin information will travel a distance l in a time $t \approx l^2/D$. In other words, a spin will know what happens to another spin a distance l away in a time t . The consequence is that a spatial inhomogeneity in the local magnetization with a characteristic length l will disappear in a time $t \approx l^2/D$. Let us put this another way: the inhomogeneity will not occur if it requires a time much longer than l^2/D to develop. A good example is the spin-lattice relaxation of protons in solid polymers at ambient temperature. In semicrystalline polymers⁶ there are at least two different intrinsic T_1 s associated with the crystalline and amorphous phases because of the difference in segmental motions of the polymer chains. However, typically, one observes only a single decay in the total magnetization $M(t)$, with a T_1^{-1} being the weighed average of the intrinsic T_1^{-1} of each phase. The reason is that the intrinsic T_1 s are much longer than the time it takes spin diffusion to occur across the domains of each phase; any inhomogeneity that would have been developed in the magnetization due to the different intrinsic T_1 s is averaged out by the spin diffusion.

On the other hand, by using appropriate NMR pulse sequences, one can create a nonuniform magnetization in a solid with a characteristic length l on a timescale much

shorter than l^2/D . Then the transfer of the magnetization by spin diffusion can be observed by NMR. Very often, the nonuniform magnetization that can be created reflects the spatial heterogeneity of the solid itself. Therefore, spin diffusion provides an useful means to study the spatial properties of disordered materials. We shall discuss more of this later.

2 EFFECTS OF SPIN DIFFUSION ON NUCLEAR SPIN RELAXATION

2.1 Spin-Lattice Relaxation by Paramagnetic Impurities

Spin diffusion in solids was first discovered¹ in spin-lattice relaxation experiments with crystalline substances, like CaF_2 , doped with paramagnetic impurities. The dipolar coupling between the electronic spin of the paramagnetic center and the nuclear spin leads to spin-lattice relaxation at the nuclear site with a rate²

$$\frac{1}{T_1(r)} = \frac{C}{r^6} \quad (11)$$

where r is the distance between the nuclear and electronic spins. It turned out that the experimental relaxation time was several orders of magnitude shorter^{1,2} than that calculated from equation (11). It was realized that, while the nuclear spins in the vicinity of the paramagnetic site relaxed very rapidly, those at a distance did not because of the r^{-6} dependence in the relaxation rate. In order for the whole spin system to relax, spin diffusion must have transported the magnetization to the vicinity of the paramagnetic sites. The time evolution of the local magnetization due to a single impurity is given by

$$\frac{\partial m(\mathbf{r}, t)}{\partial t} = D \nabla^2 m(\mathbf{r}, t) - \frac{C}{r^6} [m(\mathbf{r}, t) - m_0] \quad (12)$$

where m_0 is the thermal equilibrium value of $m(\mathbf{r}, t)$. There is a critical radius b_0 around the impurity, inside which the local magnetic field due to the electronic spin is so large that the Larmor frequencies of the nuclei there will be very different from those in the bulk of the solid, and they will escape detection. Furthermore, the large gradient in the Larmor frequency essentially quenches the spin diffusion within the critical radius b_0 , because the spin flips in the diffusion process are no longer energy-conserving.

Equation (12) can be solved either by numerical methods⁷ or by using the steady state approximation $\partial m(\mathbf{r}, t)/\partial t = 0$. To solve the steady-state equation,⁸⁻¹⁰ the following assumptions are usually made:

1. there is a 'pseudopotential' radius

$$b = 0.7(C/D)^{1/4} \quad (13)$$

around an impurity, inside which the nuclear spins relax so rapidly that the local magnetization is always at the equilibrium value;

2. the concentration ρ of the impurities is sufficiently low that the average distance $2R$ between them is much larger than b ;
3. the pseudopotential radius b is larger than the critical radius b_0 .

These assumptions can be summarized as

$$R \gg b) b_0, \quad \text{with} \quad \rho^{-1} = \frac{4}{3} \pi R^3 \quad (14)$$

By matching the boundary condition at b , the steady-state solution yields

$$1/T_1 = 4\pi \rho b D \quad (15a)$$

for $M(t)$. Equation (15a) agrees qualitatively with experimental data.² The fact that the spin–lattice relaxation depends on C as well as the diffusion coefficient D indicates that spin diffusion plays an important role in the process, but it is not the rate-determining step.

A $1/T_1$ similar to that in equation (15a) can also be obtained by an order-of-magnitude argument. It may serve to illustrate the role of spin diffusion without using complicated mathematics. As indicated in equation (11), the spin–lattice relaxation of a nuclear spin due to a paramagnetic impurity decreases very rapidly with increasing distance between them. Therefore, when the concentration of impurities is low, the spin relaxation times of the majority of the nuclear spins are much longer than the diffusion time between them, except for those within a radius b_d from the impurity. This radius b_d is determined by the condition that the spin diffusion time for the distance from the impurity to the radius b_d be of the order of $(C/b_d^3)^{-1}$. That is, $b_d^2/D \approx b_d^3/C$. This yields $b_d \approx (C/D)^{1/4} \approx b$. Because of the condition in equation (14), the number of nuclei inside the radius b_d is much smaller than that in the bulk, and can be neglected. In the limit of rapid diffusion, the spin–lattice relaxation rate of $M(t)$ is given by the weighed average of $1/T_1(r)$ in equation (11) for the nuclei outside radius b_d :

$$\begin{aligned} \frac{1}{T_1} &\approx \frac{\int_{b_d}^R C r^{-6} 4\pi r^2 dr}{\int_{b_d}^R 4\pi r^2 dr} \\ &\approx \rho \frac{4}{3} \pi (C/b_d^3) \\ &\approx \rho b D \end{aligned} \quad (15b)$$

where b_d has been replaced by b and a numerical factor of the order of unity has been neglected. Since $T_1 \approx (R^2/D)R/b$ in equation (15b), it is much longer than R^2/D , the time it takes spin diffusion to transverse a distance R . Therefore, the rapid diffusion approximation is indeed valid.

2.2 Proton Spin Relaxation via End Groups in Polymers

At low temperatures, spin–lattice relaxation of polymers occurs mainly at the end groups of the polymer chains, since the motions of the backbones of the polymers are ‘frozen’ out. End groups like methyl groups retain considerable motions even at very low temperatures, and act as sinks that relax the whole spin system by means of spin diffusion. Spin–lattice relaxation in solid n -alkanes¹¹ is a classic example of how spin relaxation is affected by the spin diffusion process. Here the role of spin diffusion can be followed mathematically, because the diffusion is essentially one-dimensional along the chain axis. Taking the center of the chain as the origin of the x axis and using the symmetry requirement $\partial m(x,t)/\partial x|_0 = 0$, the solution for $m(x,t)$ is

$$m(x,t) = \sum_{n=0}^{\infty} A_n \cos p_n x \exp(-D p_n^2 t) \quad (16)$$

For an alkane molecule of length L with N carbon atoms, the lattice constant a is roughly L/N . The boundary condition is

$$D \frac{\partial m(x,t)}{\partial x} \Big|_{x=L/2} = -\frac{am(x,t)}{T_e} \Big|_{x=L/2} \quad (17)$$

which equates the flux of the magnetization to the methyl group to the rate $1/T_e$ by which the magnetization is relaxed by the rotation of the methyl group. This leads to the equation

$$\frac{1}{2} L p_n \tan \frac{1}{2} L p_n = \frac{La}{2DT_e} \quad (18)$$

which relates p_n to the length of the chain, the diffusion coefficient, and the relaxation rate at the end group.

In the limit of rapid spin diffusion, i.e., $DT_e \gg L^2$, we have

$$p_n^2 = \frac{2}{N D T_e} \quad (19)$$

Since all the terms in the sum in equation (16) have the same time constant, the spin–lattice relaxation rate of $M(t)$ is

$$\begin{aligned} T_L^{-1} &= D p_n^2 \\ &= (2/N)(T_e)^{-1} \end{aligned} \quad (20)$$

which is the weighed average of the relaxation rate at the end groups. The factor of 2 is due to the fact that there are two methyl groups in each alkane molecule.

On the other hand, in the opposite limit of $DT_e \ll L^2$, where now the spin diffusion is the rate limiting step, one has instead

$$p_n \approx (2n+1)\pi/L \quad (21)$$

Because of the n dependence of p_n , only the first term in the sum in equation (16) is important, and the spin–lattice relaxation rate becomes

$$T_L^{-1} = D(\pi/aN)^2 \quad (22)$$

It is independent of T_e ! One important difference between the spin–lattice relaxation rates in the fast and slow diffusion limits is their dependence on the size of the molecules. The former is proportional to N^{-1} , while the latter has a N^{-2} dependence. Experimentally, the spin–lattice relaxation rate in the rotating frame $T_{1\rho}^{-1}$ of n -alkanes¹¹ at -190°C was found to have an $N^{-1.7}$ dependence. This indicates that the spin–lattice relaxation in the rotating frame is governed, to a large extent, by how fast the local magnetization is transported by spin diffusion to the end groups.

2.3 Proton Spin Relaxation in Semicrystalline Polymers in the Rotating Frame

The above discussion can be extended to ^1H spin relaxation in semicrystalline polymers at ambient temperature. The polymers consist of domains of crystalline and amorphous phases. Owing to different backbone motions available at ambient temperature, each phase has a different intrinsic T_1 and $T_{1\rho}$. Since the proton spin–spin interactions may be different, different spin diffusion coefficients can also be assigned to the two phases. Because the T_1 s are typically

Figure 1 A two-phase, one-dimensional model of spin diffusion in a polymer. The multiple domain arrangement on the left is reduced to a two-domain system with a cyclic boundary condition

much longer than the spin diffusion time across a domain, only a simple exponential decay is observed in the total magnetization, with T_1^{-1} being the weighed average of the intrinsic $T_{1\rho}^{-1}$ s. However, the $T_{1\rho}$ s are found to be sufficiently short that the spatial averaging by spin diffusion is not complete, and multiple component decay can be observed.^{6,12,13} To treat the effects of spin diffusion on $T_{1\rho}$ in the general case would require solving the diffusion equation numerically. To simplify the matter, the following approximations are often made.

1. The domains have the form of parallel layers. The spin diffusion is one-dimensional perpendicular to the layers.
2. Only one domain of each of the crystalline and amorphous phases is considered. They are arranged in such a way that they are joined to each other at both ends.

This arrangement is depicted in Figure 1. Pairs of diffusion coefficients D_1 and D_2 , intrinsic relaxation times $T_{1\rho}(1)$ and $T_{1\rho}(2)$, and thicknesses l_1 and l_2 are assigned to the amorphous and crystalline layers, respectively.

To see how the spin diffusion affects the spin relaxation times, let us consider the case in which the spin relaxation time $T_{1\rho}(1)$ of the amorphous phase is short and satisfies the condition $T_{1\rho}(1) \ll T_{1\rho}(2)$, l_1^2/D_1 and l_2^2/D_2 . This amounts to treating the amorphous phase as a sink that relaxes the magnetization of the crystalline phase via spin diffusion. At the same time, the magnetization in the crystalline phase is also relaxed by the direct coupling to the lattice, with a rate $1/T_{1\rho}(2)$. Define the center of the crystalline layer as the origin of the x axis. The spin diffusion equation in the crystalline region is

$$\frac{\partial m(x, t)}{\partial t} = D_2 \frac{\partial^2 m(x, t)}{\partial x^2} - \frac{m(x, t)}{T_{1\rho}(2)} \quad \text{for} \quad -\frac{1}{2}l_2 < x < \frac{1}{2}l_2 \quad (23)$$

The substitution

$$m(x, t) \equiv \exp[-t/T_{1\rho}(2)] m^*(x, t) \quad (24)$$

reduces equation (23) to the one-dimensional diffusion equation for $m^*(x, t)$, but now without the decay term. The solution of $m^*(x, t)$ has the same form as that on the right-hand side of equation (16). The condition $T_{1\rho}(1) \ll T_{1\rho}(2)$ and l_1^2/D_1 indicates that the magnetization relaxes uniformly across the amorphous domain, which leads to the same boundary condition for $m^*(x, t)$ as that in equation (17) except that

T_e is replaced by $T_{1\rho}(1)$ and L by l_2 . The diffusion problem is therefore reduced to that of the spin relaxation via the end groups described earlier. Furthermore, because $T_{1\rho}(1)$ is much shorter than l_2^2/D_2 , the coefficient p_n is given by the diffusion limiting solution in equation (21). With equation (24), one finds that the relaxation time constants of the multiple component decay of the total magnetization are $T_{1\rho}(1)$ and the $T_{1\rho}(2, n)$ s, where

$$\frac{1}{T_{1\rho}(2, n)} = \frac{1}{T_{1\rho}(2)} + \frac{D_2(2n+1)^2\pi^2}{l_2^2} \quad (25)$$

with $n = 0, \dots, \infty$. The relative intensities of the decay components associated with each $T_{1\rho}(2, n)$ are directly proportional to $(2n+1)^{-2}$. If $T_{1\rho}(2)$ is much longer than l_2^2/D_2 then only the $T_{1\rho}(2, n=0)$ term is important, and the number of components in the decay is reduced to two: one with a time constant $[1/T_{1\rho}(2) + D_2\pi^2/l_2^2]^{-1}$ and the other with $T_{1\rho}(1)$. It is important to realize that when more than one $T_{1\rho}(2, n)$ contribute to the decay of $M(t)$, the intensities of these components in the decay have no direct relationship to the number of nuclei contributing to them.

The dependence of $T_{1\rho}(2, n)$ on l_2 suggests that the domain size in polymers may be extracted indirectly from the proton spin relaxation measurements. In the general case, one may solve the diffusion equation numerically and fit the results to the experimental data.^{12,13} In the special case where $T_{1\rho}(1) \ll T_{1\rho}(2)$, l_1^2/D_1 and l_2^2/D_2 , the data are simply fitted with a multiple component decay with the time constants given by equation (25). $T_{1\rho}(1)$, $T_{1\rho}(2)$, and l_2 are usually treated as the adjustable parameters.¹⁴

3 STUDIES OF POLYMER MORPHOLOGY BY PROTON SPIN DIFFUSION

Information about domain size can be obtained directly using the Goldman–Shen method.¹⁵ This is based on the idea that with appropriate NMR pulse sequences, nonuniform magnetization associated with the spatial inhomogeneity of a solid can be created on a timescale much shorter than that of the spin diffusion. By monitoring the return of the magnetization to the uniform state by spin diffusion, the sizes of the spatial inhomogeneities can be deduced. As the most

Figure 2 The Goldman–Shen NMR pulse sequence. The magnetization in the crystalline phase is randomized in a time t_0 . The transfer of magnetization by spin diffusion from the amorphous domain to the crystalline one occurs during the time t

abundant and strongly coupled spin in polymers, ^1H is usually the nucleus of choice for such studies.

The original Goldman–Shen pulse sequence $[(\frac{1}{2}\pi)_x - t_0 - (\frac{1}{2}\pi)_x - t - (\frac{1}{2}\pi)_x]$ was first applied to homopolymers with rigid and mobile phases.^{16–18} We shall use semicrystalline polymers as an example for our discussion. To a large extent, the free induction decay (FID) of semicrystalline polymers consists of two components associated with the crystalline (rigid) and amorphous (mobile) phases. The spin–spin relaxation time T_2 of the crystalline domain is usually shorter than that of the amorphous domain. By decomposing the FID with curve fitting techniques, one determines the fraction of the total proton magnetization in each phase. The Goldman–Shen pulse sequence shown in Figure 2 exploits this difference. After the initial $(\frac{1}{2}\pi)_x$ pulse, one waits for a fixed time t_0 during which the total magnetization of the crystalline phase M_2 is allowed to decay to zero while there is still sufficient magnetization left in the amorphous phase. The second pulse returns the remaining magnetization M_1 in the amorphous phase to the direction of the external magnetic field. The magnetization in the amorphous phase is allowed to diffuse back to the crystalline phase for a variable time t . By decomposing the FID observed after the third pulse, one determines the amount of magnetization that has been transferred back to the crystalline phase. The spin diffusion period t should be shorter than the T_1 of the system, so that the return of the magnetization to the crystalline phase is due to spin diffusion and not because of spin–lattice relaxation. The sizes of domain structures suitable for spin diffusion studies are those which the spin diffusion can transverse in a time of the order of T_1 . For a typical T_1 of the order of 0.1 s and ^1H spin diffusion coefficient of $6 \times 10^{-12} \text{ cm}^2 \text{ s}^{-1}$, they are about 8 nm.

The recovery of the magnetization in the crystalline phase is defined as

$$\begin{aligned} \Gamma(t) &= \frac{M_2(t)}{M_2(t \rightarrow \infty)} \\ &= 1 - \frac{M_1(t) - M_1(t \rightarrow \infty)}{M_1(t=0) - M_1(t \rightarrow \infty)} \end{aligned} \quad (26)$$

Figure 3 The recovery of the magnetization $\Gamma(t)$ in the crystalline phase of a polypropylene film as a function of the diffusion time t . The experimental data are represented by the solid circles. The theoretical fit according to equations (30) and (31) is given by the solid line

An example of $\Gamma(t)$ for polypropylene film is shown in Figure 3. To extract spatial information from $\Gamma(t)$, one needs to solve the diffusion equation according to the initial and boundary conditions appropriate to the problem. In general, solutions can be obtained only by numerical methods,¹⁹ even for the simplest polymer models. Fortunately, analytical solutions are available if one assumes either (i) that the diffusion coefficient is the same for both the amorphous and crystalline phases or (ii) that the diffusion coefficient of the crystalline phase is much shorter than that of the amorphous phase.

The solution to the first case is described in detail by Cheury and Gerstein.¹⁸ We shall present a simplified account here. Again, we consider the model given in Figure 1. Let the center of the amorphous domain be the origin of the x axis. The amorphous domain occupies the region $-\frac{1}{2}l_1 < x < \frac{1}{2}l_1$, while the crystalline domain extends from $-\frac{1}{2}l_1$ to $-\frac{1}{2}(l_1 + l_2)$ and from $\frac{1}{2}l_1$ to $\frac{1}{2}(l_1 + l_2)$. For simplicity, we shall assume that l_2 is much larger than l_1 , which is appropriate when the polymer has a high degree of crystallinity. With the initial conditions

$$m(x, t=0) = \begin{cases} 1 & \text{for } x \in \text{amorphous phase} \\ 0 & \text{for } x \in \text{crystalline phase} \end{cases} \quad (27)$$

and the boundary condition

$$\left. \frac{\partial m(x, t)}{\partial x} \right|_{x=\pm(l_1+l_2)/2} = 0 \quad (28)$$

one obtains

$$\begin{aligned} \psi(t) &\equiv \int_{-l_1/2}^{l_1/2} [m(x, t) - m(x, t \rightarrow \infty)] dx \\ &= \frac{8}{l_1 + l_2} \sum_{n=1}^{\infty} \frac{\sin^2(\frac{1}{2}p_n l_1)}{p_n^2} \exp(-Dp_n^2 t), \quad \text{with } p_n = \frac{2\pi n}{l_1 + l_2} \\ &\approx l_1 \left\{ 1 - \int_0^t d\tau \left(\frac{D}{\pi l_1^2 \tau} \right)^{1/2} \left[1 - \exp\left(-\frac{l_1^2}{4D\tau}\right) \right] \right\} \\ &\quad \text{for } l_1 \ll l_2 \end{aligned} \quad (29)$$

For a single layer of the amorphous and crystalline phase, $\Gamma(t) = 1 - \psi(t)/\psi(0)$. This expression for $\Gamma(t)$ is applicable to oriented polymers with lamellar domains. However, if the distribution of the domains is isotropic, spin diffusion in each of the directions (whether along the x , y , or z axis) is equivalent. The general form of $\Gamma(t)$, taking this into account, is

$$\Gamma(t) = 1 - [\psi(t)/\psi(0)]^3 \quad (30)$$

In semicrystalline polymers, there is always a distribution of the width of the domains. The result in equation (29) amounts to assuming a delta function for the distribution of l_1 . On the other hand, averaging equation (29) over a Poisson distribution $(1/\langle l_1 \rangle) \exp(-l_1/\langle l_1 \rangle)$ for l_1 , where $\langle l_1 \rangle$ is the average l_1 , $\psi(t)/\psi(0)$ becomes

$$\frac{\psi(t)}{\psi(0)} = \exp\left(\frac{Dt}{\langle l_1 \rangle^2}\right) \operatorname{erfc}\left(\sqrt{\frac{Dt}{\langle l_1 \rangle^2}}\right) \quad (31)$$

where erfc is the complementary error function. Regardless of the form of the distribution of l_1 , the short-time behavior of $\Gamma(t)$ depends only on $\langle l_1 \rangle$, the average value of l_1 . This can be seen by expanding equation (29) in the limit of small t and substituting the result into equation (30):

$$\Gamma(t) = \frac{6}{\sqrt{\pi}} \left(\frac{Dt}{\langle l_1 \rangle^2}\right)^{1/2} \quad \text{for } t \ll \frac{\langle l_1 \rangle^2}{D} \quad (32)$$

In Figure 3, equation (30) with $\psi(t)/\psi(0)$ given by equation (31) is fitted to the data for the polypropylene film. For $D = 6.75 \times 10^{-12} \text{ cm}^2 \text{ s}^{-1}$, a value of $\langle l_1 \rangle = 4.9 \text{ nm}$ is obtained from the fit.

In block copolymers¹³ and polymer blends,⁶ one sometimes encounters two polymers with very different T_2 s. The approximation of a single spin diffusion coefficient is clearly invalid. In this case, one may consider the two-domain model in Figure 1 in the limits

$$D_1 \ll D_2, \quad l_1 \ll l_2 \quad (33)$$

where subscripts 1 and 2 represent the phases with long and short T_2 , respectively. We shall refer to these as the slow and fast diffusion domains. With the conditions in equation (33), the spin diffusion in the slow domain is again reduced to the diffusion limiting case of what we have discussed for spin relaxation via end groups. With the initial condition that there is only magnetization in the slow diffusion region, one obtains

$$\begin{aligned} \frac{\psi(t)}{\psi(0)} &= \sum_{n=0}^{\infty} \frac{8}{(2n+1)^2 \pi^2} \exp\left[-D_1 \left(\frac{2n+1}{l_1}\right)^2 \pi^2 t\right] \\ &\approx 1 - \frac{4}{\sqrt{\pi}} \left(\frac{D_1 t}{l_1^2}\right)^{1/2} \quad \text{for } t \ll l_1^2/D_1 \end{aligned} \quad (34)$$

The recovery of the magnetization in the fast diffusion domain (assuming isotropic distribution of the domains and spin diffusion in three directions) becomes

$$\Gamma(t) = \frac{12}{\sqrt{\pi}} \left(\frac{D_1 t}{l_1^2}\right)^{1/2} \quad \text{for } t \ll l_1^2/D_1 \quad (35)$$

which should be compared with equation (32). As a function of $\sqrt{t}$, the slope of $\Gamma(t)$ in equation (35) is twice as large as that in equation (32). [The short-time ($t \ll l_1^2/D_1$) result in equation (34) is slightly different from that in equation (17) of Cheung and Gerstein.¹⁸ The latter is based on the

transfer of magnetization from the slow diffusion domain to the fast diffusion one at only one interface between the domains. However, the transfer in the two-domain model in Figure 1 occurs at two interfaces. The result is that the slope of $\Gamma(t)$ as a function of $\sqrt{t}$ in equation (35) is twice as large as that obtained from equation (17) of Cheung and Gerstein.¹⁸] We can summarize the results in both equations (32) and (35) by the following statement. In the Goldman–Shen experiment, the *initial* return of the magnetization to the domain, which has been depleted of magnetization, increases linearly with $\sqrt{t}$, and the slope is proportional to $(D/l^2)^{1/2}$, with D and l being the spin diffusion coefficient and the size of the domain from which the magnetization emanates.

Several modifications of the Goldman–Shen pulse sequence have been proposed. Two of the significant ones are

1. the use of multiple pulse techniques^{19,20} to suppress spin diffusion during the creation of the nonuniform magnetization (i.e., in the time window t_0) and to enhance the ^1H spectral resolution at the detection period;²¹
2. identification of domains with ^{13}C NMR after ^1H – ^{13}C cross polarization.^{22–24}

The latter is used in the detection period, and is particularly suitable for polymer blends²⁵ consisting of two polymers with very different structures.

1 INTRODUCTION

While solution NMR methods have been successfully applied for elucidating three dimensional (3D) structures of molecules including proteins (see **Biological Macromolecules: Structure Determination in Solution**, Volume 2), solid-state NMR has not attained such a stage. This review demonstrates the state of the art of structural determination of a whole molecule by solid state NMR, which should be complementary to solution NMR and irreplaceable for insoluble systems. In NMR of solids, measurements of dipolar interactions provide direct information on geometrical structures; they are most conveniently made under magic angle spinning (MAS) (see **Magic Angle Spinning**, Volume 5) with hidden potential of determining more than one distance using a single sample. However, most of the methods developed so far are of non-selective measurements of dipolar couplings, by which it is difficult to deduce quantitative structural information when more than two spins are involved. Hence, only one specific internuclear distance or dihedral angle is commonly determined by selectively isotope-labeling a particular pair of atoms. Then, many doubly-labeled samples must be prepared, if one tries to determine the 3D structure composed of sizable atoms by such non-selective approaches. On the other hand, if a specific dipolar interaction in a multiply or uniformly labeled system can selectively be recoupled, all the structural parameters necessary to determine the 3D structure can be obtained one by one using a single sample, significantly saving labor for sample preparation.

To achieve frequency-selective recoupling, it is required to remove all dipolar couplings at once, and recouple a

specific pair. Using MAS, one can remove all the dipolar couplings together with chemical shift anisotropies under proton decoupling, and therefore the remaining problem is to achieve selective recoupling under MAS fast enough to remove all the other dipolar interactions simultaneously. For homonuclear dipolar interactions, rotational resonance (R^2)¹⁻⁸ has been developed as a simple selective recoupling method, and in fact, has been applied to biologically interesting molecules.⁹ In the R^2 method, selection of a pair of spins is made by adjusting an integral multiple of the MAS frequency ν_R to the difference of the chemical shifts of the two spins. Therefore, R^2 is frequency-difference selective, and if more than one spin pair with the same separation exists, they are simultaneously recoupled. Further, when the chemical shift difference for the two spins is relatively small, the MAS frequency must be lowered, leading to imperfect decoupling of the other dipolar interactions.

Selective recoupling among homonuclear spins can also be achieved in a tilted rotating frame.¹⁰ Under rf irradiation, the Zeeman interaction for a spin system can be written in a tilted rotating frame (X, Y, Z) as

$$\frac{\mathcal{H}}{\text{Hz}} = \sum_i \nu_{ei} \hat{I}_{Zi} \quad (1)$$

while the conventional Zeeman interaction in the rotating frame (x, y, z) is written as

$$\mathcal{H} = \sum_i \Delta \nu_i \hat{I}_{zi} \quad (2)$$

where ν_e denotes the effective field and $\Delta \nu$ is the resonance offset. By comparing these two equations, it may be expected that the R^2 condition in the rotating frame:

$$|\Delta \nu_1 - \Delta \nu_2| = n \nu_R \quad (3)$$

would be modified in the tilted rotating frame as

$$|\nu_{e1} - \nu_{e2}| = n \nu_R \quad (4)$$

In fact, this is one of the recoupling conditions in the tilted rotating frame. There are additional recoupling conditions, namely, $\nu_{e1} + \nu_{e2} = n \nu_R$ and $\nu_{eX} = n \nu_R$ ($X = I$ or S), as derived in the following section. These conditions are referred to as the R2TR (rotational resonance in the tilted rotating frame) conditions. There are three adjustable parameters to achieve one of the R2TR conditions, namely, the intensity ν_1 and the frequency ν of the rf irradiation and the MAS frequency ν_R . This diversity makes it possible to find an R2TR condition even for a pair of spins with a small chemical shift difference without relaxing the fast MAS condition necessary for decoupling all other dipolar couplings. Further, it should be pointed out here that, while R^2 is frequency-difference selective, R2TR is frequency selective. Hence, a particular dipolar coupling can be recoupled by properly choosing the experimental parameters even when more than two lines have equal chemical-shift differences.

2 THEORY

First, we briefly touch upon rotational resonance recoupling. A dipolar-coupled homonuclear two-spin $I-S$ system in a

2 NUCLEAR INTERACTIONS

rotating powdered sample is considered. For simplicity, the chemical shift anisotropies (CSAs) are neglected. The total spin Hamiltonian can be written as

$$\mathcal{H} = \Delta \nu_I \hat{I}_z + \Delta \nu_S \hat{S}_z + \mathcal{H}_D(t) \quad (5)$$

where $\mathcal{H}_D(t)$ is the homonuclear dipolar interaction

$$\mathcal{H}_D(t) = D(t) \left\{ \hat{I}_z \hat{S}_z - \frac{1}{4} (\hat{I}_+ \hat{S}_- + \hat{I}_- \hat{S}_+) \right\} \quad (6)$$

with the spatial part modulated by MAS

$$D(t) = \sum_{n=\pm 1, \pm 2} \nu_{Dn} \exp(in \nu_R t) \quad (7)$$

Here, ν_{Dn} is a function of the internuclear distance and the polar angles defining the direction of the $I-S$ vector in a rotor-fixed frame. $\mathcal{H}_D(t)$ is transferred into the frame of the Zeeman interaction by using the unitary operator

$$U(t) = \exp(i \Delta \nu_I \hat{I}_z t) \exp(i \Delta \nu_S \hat{S}_z t) \quad (8)$$

as

$$\begin{aligned} \widetilde{\mathcal{H}}_D(t) &= U(t) \mathcal{H}_D(t) U^{-1}(t) \\ &= \sum_{n=\pm 1, \pm 2} \nu_{Dn} \left[\hat{I}_z \hat{S}_z \exp(in \nu_R t) \right. \\ &\quad \left. - \frac{1}{4} (\hat{I}_+ \hat{S}_- + \hat{I}_- \hat{S}_+) \exp\{i(n \nu_R - \Delta)t\} \right] \end{aligned} \quad (9)$$

where Δ is the difference of the isotropic chemical shift: $\Delta = \nu_I - \nu_S$. This equation shows that the rotational resonance recoupling occurs at $\Delta = n \nu_R$ with $n = \pm 1, \pm 2$. If one takes account of the chemical shift anisotropies, one can prove that recoupling occurs even under higher-order ($|n| > 2$) conditions.⁴

Second, we examine the effect of continuous wave rf irradiation along the x -axis of the rotating frame for the two-spin system. The total Hamiltonian

$$\mathcal{H} = \Delta \nu_I \hat{I}_z + \Delta \nu_S \hat{S}_z + \nu_1 (\hat{I}_x + \hat{S}_x) + \mathcal{H}_D(t) \quad (10)$$

is transformed into the tilted rotating frame (X, Y, Z) by the unitary transformation of

$$U_{TR} = \exp(i \beta_I \hat{I}_y) \exp(i \beta_S \hat{S}_y) \quad (11)$$

where β_X denotes the angle between the z -axis of the rotating frame (i.e., the direction of the static field) and the Z -axis of the tilted rotating frame (i.e., the direction of the effective field) for the X spin. The total spin Hamiltonian in the tilted rotating frame can be given by

$$\begin{aligned} \mathcal{H}^{TR} &= U_{TR} \mathcal{H} U_{TR}^{-1} \\ &= \nu_{eI} \hat{I}_Z + \nu_{eS} \hat{S}_Z + U_{TR} \mathcal{H}_D(t) U_{TR}^{-1} \end{aligned} \quad (12)$$

where ν_{eX} denotes the strength of the effective field for the X spin. This is further transferred into the interaction frame using the following unitary operator

$$U_{\text{eff}}(t) = \exp(i \nu_{eI} \hat{I}_Z t) \exp(i \nu_{eS} \hat{S}_Z t) \quad (13)$$

and the result is

$$\begin{aligned} \mathcal{H}_D^*(t) &= U_{\text{eff}}(t) U_{TR} \mathcal{H}_D(t) U_{TR}^{-1} U_{\text{eff}}^{-1}(t) \\ &= \sum_{n=\pm 1, \pm 2} \nu_{Dn} [A \hat{I}_Z \hat{S}_Z \exp(-in \nu_R t) \\ &\quad + B [\hat{I}_+ \hat{S}_- \exp\{i(n \nu_R + \Delta_{\text{eff}})t\} \\ &\quad + \hat{I}_- \hat{S}_+ \exp\{i(n \nu_R - \Delta_{\text{eff}})t\}] \\ &\quad + R [\hat{I}_Z \hat{S}_+ \exp\{i(n \nu_R + \nu_{eS})t\} \\ &\quad + \hat{I}_Z \hat{S}_- \exp\{i(n \nu_R - \nu_{eS})t\}] \\ &\quad + S [\hat{I}_+ \hat{S}_Z \exp\{i(n \nu_R + \nu_{eI})t\} \\ &\quad + \hat{I}_- \hat{S}_Z \exp\{i(n \nu_R - \nu_{eI})t\}] \\ &\quad + Q [\hat{I}_+ \hat{S}_+ \exp\{i(n \nu_R + \Sigma_{\text{eff}})t\} \\ &\quad + \hat{I}_- \hat{S}_- \exp\{i(n \nu_R - \Sigma_{\text{eff}})t\}]] \end{aligned} \quad (14)$$

where the coefficients A , B , R , S , and Q are functions of the angle β_X , whose explicit forms are found in Ref.¹¹. It can be shown that the spatial part of $\mathcal{H}_D^*(t)$ is modulated by MAS with the spinning frequency ν_R and $2\nu_R$, while the spin part is modulated by the effective field with the frequencies of $\Sigma_{\text{eff}} = \nu_{eI} + \nu_{eS}$, $\Delta_{\text{eff}} = \nu_{eI} - \nu_{eS}$, ν_{eI} , and ν_{eS} . When any of the conditions Σ_{eff} , Δ_{eff} , ν_{eI} , or $\nu_{eS} = m \nu_R$ ($m = \pm 1$ or ± 2) is met, the time dependence of the spatial part and the spin part in $\mathcal{H}_D^*(t)$ is partially canceled with each other to give a static dipolar interaction $\overline{\mathcal{H}}_D^*$.

3 METHOD

Determination of the 3D structure of a multiply labeled molecule can be accomplished by obtaining all bond lengths, bond angles, and dihedral angles. For a peptide, however, one may use typical bond lengths and angles because they differ only slightly among peptides, and the peptide 3D structure can be constructed by determining dihedral angles.

Figure 1 illustrates the strategy. For a multiply $^{13}\text{C}/^{15}\text{N}$ labeled peptide, all dipolar interactions are removed uniformly by fast MAS and proton decoupling. Then, a specific three-bonds distant pair of spins is selectively recoupled by applying an rf field satisfying a proper R2TR condition. The time development of the magnetization of either of the paired spins is measured, from which the corresponding dihedral angle is deduced. This procedure is repeated for other spin pairs, until all the dihedral angles are determined.

The pulse sequence for the selective recoupling experiments is shown in Figure 2(a). During the recoupling period (t_m), the rf field satisfying a R2TR condition $\nu_{eI} + \nu_{eS} = \nu_R$ is applied to one of the paired spins concerned. This rf field also functions for spin-locking the magnetization. Then, the t_m dependence of the spin-locked magnetization is monitored after removing the possible small y component of the magnetization by applying a 90_X° pulse. The t_m dependence of the magnetization is also affected by $T_{1\rho}$ relaxation. Measuring $T_{1\rho}$ under the same irradiation condition but with a slightly (~ 500 Hz) different spinning frequency so as not to satisfy the DQ R2TR condition, we can remove the relaxation effect from the t_m dependence by multiplying it by $\exp(t_m/T_{1\rho})$.

Figure 1 Schematic illustration of uniform decoupling by MAS and selective recoupling

The other conditions of ZQ, SQ, and DQ ($n > 1$) are not suitable for the present experiments for the following reasons. First, to satisfy a ZQ condition, the chemical shift difference between a specific pair of spins must be larger than ν_R . However, chemical shift differences of ^{13}C or ^{15}N spin pairs at a common magnetic-field intensity are not so large as to satisfy a ZQ condition for ν_R fast enough to completely decouple the other dipolar couplings. Second, under a SQ condition, both chemical shift anisotropies (CSAs) of the relevant carbons are dominantly recovered, obscuring the effect of dipolar recoupling. Last, a DQ condition with $n > 1$, which requires a large rf-field intensity for ν_R fast enough to decouple the other dipolar couplings, lowers the selectivity of recoupling.

The influence of intermolecular dipolar couplings on the dipolar recoupling experiments was reduced by diluting a uniformly labeled sample (10%) with natural abundance material (90%). In the recoupling-time dependence experiments for the 10% uniformly labeled sample, 10% of the signal intensity at $t_m = 0$ was subtracted from the intensity observed at each recoupling time t_m , because it was found that the magnetization of the natural abundance material is kept almost constant during t_m .

An alternative approach to determine a dihedral angle is to measure mutual orientations of two or more anisotropic spin interactions. In the R2TR method, one can easily and quickly switch the dipolar interaction to be recoupled from one to another by changing ν and ν_1 under a constant spinning speed contrary to the normal R^2 method. This makes it possible to realize a 2D experiment which correlates the AB and CD dipolar powder patterns in an A–B–C–D ^{13}C

Figure 2 Pulse sequences to determine dihedral angles. (a) Dipolar recoupling experiment. After CP, a rf field satisfying a DQ condition for a particular pair of ^{13}C spins is applied on resonance to one of the spins for a recoupling time t_m . Then, the transverse magnetization of the spin is observed as a function of t_m . (b) 2D dipolar correlation experiment. After CP, the C magnetization in a four ^{13}C spin (A–B–C–D) system is suppressed by a DANTE pulse train. The A–B and the C–D dipolar interactions are selectively recovered in the t_1 and t_2 periods, respectively. These dipolar powder patterns are correlated by transferring magnetization from A or B to C or D in the mixing period. The AB/CD dipolar correlation spectrum is obtained by observing the C magnetization in the detection period t_3 . (Reproduced from Nomura et al.¹³ with kind permission from Kluwer Academic Publishers)

spin system. Figure 2(b) shows the pulse sequence for the 2D dipolar correlation experiment. After cross polarization (CP), the C magnetization is suppressed by a selective 90° (DANTE) pulse followed by a dephasing period (t_d). In the first evolution period (t_1) the AB dipolar interaction is selectively recoupled, in the mixing period the A or B magnetization is selectively transferred to the C or D spin, and in the second evolution period (t_2) the C magnetization evolves under the selectively recoupled CD dipolar interaction. The AB/CD dipolar correlated 2D powder pattern is selectively obtained by observing the C spin in the detection period (t_3).

Recoupling may take place even in off-R2TR conditions to some extent, making the selectivity incomplete. The incompleteness of selectivity can be taken into account by including several spins into simulations in addition to the relevant two spins. To examine selectivity, we studied magnetization transfer in uniformly ^{13}C labeled L-alanine.¹¹ Figure 3(a) shows the ^{13}C 2D exchange NMR spectrum observed without applying any ^{13}C rf field during a mixing time of 4 ms under a MAS frequency of 5718 Hz. No conventional R^2 effects were observed at this spinning speed. The spectrum in Figure 3(b)

Figure 3 ^{13}C 2D exchange NMR spectra of uniformly ^{13}C labeled L-alanine. It was observed (a) without and (b) with applying a ^{13}C rf field during a mixing time of 4 ms under the MAS frequency of 5718 Hz. The rf field with the intensity of 4 kHz was applied at 296.7 ppm for the spectrum (b) to satisfy a R2TR condition $\Delta_{\text{eff}} = 2\nu_{\text{R}}$ for the carboxyl and the methyl carbons

was obtained at the same spinning speed while applying an rf field with the intensity of 4 kHz during the same mixing time to satisfy the ZQ R2TR condition $\Delta_{\text{eff}} = 2\nu_{\text{R}}$ for the carboxyl and methyl ^{13}C spins. Cross peaks appear between the carboxyl and methyl carbons, but no cross peaks can be seen between the carboxyl and methine carbons or between the methine and methyl carbons. This result confirms that the dipolar interaction between the carboxyl and the methyl carbons can be selectively recovered by the R2TR experiment, in spite of the fact that the recoupled dipolar coupling is below one fourth the other couplings. The stronger couplings remain completely decoupled by MAS.

Figure 4 shows the observed and the calculated mixing-time dependence of the individual ^{13}C magnetizations after saturation of the methyl carbon signal. The initial rapid oscillation of the carboxyl ^{13}C magnetization can be ascribed to the spinning sidebands in the tilted rotating frame,¹¹ which is damped quickly within a few milliseconds due to rf-field inhomogeneity. Hence, in the following, this oscillation in the simulation was damped to the same extent as the experimental data. Except for this initial oscillation and slight decay due to relaxation, the sum of the ^{13}C magnetizations of the carboxyl and the methyl carbons, $M_{0I} + M_{0S}$, is shown to be conserved. Further, the observed and the calculated curves for the methine carbon in Figure 4(b) again shows that the polarization transfer occurs selectively between the carboxyl and the methyl carbons, and further that a mixing time of 5 ms is enough for the polarization transfer between two carbons separated by 0.25 nm.

Further, to examine how large the chemical shift difference between non-relevant spins should be to achieve high selectivity, several isotropic chemical-shift values were assumed for the methine carbon, keeping its chemical shift anisotropy constant. Figure 5 shows the calculated mixing-time dependence of the methine ^{13}C magnetization for four chemical shift differences between the methyl and the methine carbons: 0, 500, 1000, and 2340 Hz. From Figure 5, it can be concluded that the chemical shift difference should be larger than 1000 Hz for selective transfer, leading to the following practical criteria of spins being added in simulations: For the selective recoupling experiment of A and D in a A–B–C–D ^{13}C system with observing the D magnetization, not only all the four spins, but also the following ^{13}C spin(s), if any: ^{13}C directly bonded to D (A), and ^{13}C within about 0.25 nm from D (A)

with the ν_{e} difference between the ^{13}C and A (D) less than 1000 Hz.

4 APPLICATION TO GLYCYLISOLEUCINE

In the following, the complete 3D structure of a glycyloisoleucine (Gly-Ile) molecule by R2TR is determined using a powder sample of uniformly ^{13}C , ^{15}N -labeled Gly-Ile molecules, including all the positions of carbons, nitrogens, and oxygens in both main and side chains.^{12,13} The 3D structure of a Gly-Ile molecule is obtained by measuring the six dihedral angles shown in Figure 6. In this study, ψ_{G} , ω_{G} , ϕ_{I} , χ_{I1} , and χ_{I2} are defined as dihedral angles $\text{N}_{\text{G}}-\text{C}_{\text{G}}^{\alpha}-\text{C}_{\text{G}}^{\beta}-\text{N}_{\text{I}}$, $\text{C}_{\text{G}}^{\alpha}-\text{C}_{\text{G}}^{\beta}-\text{N}_{\text{I}}-\text{C}_{\text{I}}^{\alpha}$, $\text{C}_{\text{G}}^{\beta}-\text{N}_{\text{I}}-\text{C}_{\text{I}}^{\alpha}-\text{C}_{\text{I}}^{\beta}$, $\text{C}_{\text{I}}^{\alpha}-\text{C}_{\text{I}}^{\beta}-\text{C}_{\text{I}}^{\gamma 1}-\text{C}_{\text{I}}^{\delta}$, and $\text{C}_{\text{I}}^{\alpha}-\text{C}_{\text{I}}^{\beta}-\text{C}_{\text{I}}^{\gamma 1}-\text{C}_{\text{I}}^{\delta}$, respectively, by taking zero degrees for the *cis* conformation. ψ_{I} is defined as the angle between the $\text{N}_{\text{I}}-\text{C}_{\text{I}}^{\alpha}$ bond and the $\text{O}_{\text{I}}^1-\text{C}_{\text{I}}^{\gamma 1}-\text{O}_{\text{I}}^2$ plane, being between 0 and 180°. ψ_{G} , ω_{G} , ϕ_{I} , and χ_{I1} were determined by performing the R2TR dipolar recoupling experiment for a proper three or four-bonds distant spin pair, and χ_{I2} by a 2D dipolar correlation experiment because of the reason mentioned later, assuming the typical bond lengths and angles shown in Figure 6. The planar configuration of the peptide plane was also assumed.

Although the CSA interaction was neglected in Theory for simplicity, it does contribute to the results, and should thus be included into numerical calculations. Especially, the contribution of the CSA tensors for carbonyl carbons and amide nitrogens in the main chain are important owing to their large anisotropies (see **Chemical Shift Tensors**, Volume 2). However, the CSA tensors for carbonyl carbons are not very different from peptide to peptide. Hence, the mean values of δ and η for the carbonyl carbon tensors reported for some peptides are adopted (Table 1). For the directions of the principal axes, it is generally observed that the σ_{33} axis is perpendicular to the sp^2 plane.¹⁴ On the other hand, the σ_{22} axis may make a small angle with the C=O bond direction. For $\text{C}_{\text{G}}^{\beta}$, the σ_{33} axis is assumed to be perpendicular to the sp^2 plane and the σ_{22} axis makes the angle of 4.5° with the $\text{C}_{\text{G}}^{\beta}-\text{O}_{\text{G}}$ bond toward the $\text{C}_{\text{G}}^{\beta}-\text{C}_{\text{G}}^{\alpha}$ bond.¹⁵ For $\text{C}_{\text{I}}^{\alpha}$, the σ_{33} axis is perpendicular to the sp^2 plane and the σ_{11} axis is along the $\text{C}_{\text{I}}^{\alpha}-\text{C}_{\text{I}}^{\beta}$ bond. The δ and η values for N_{I} and N_{G} were

Figure 4 Experimental (○) and simulated (—) mixing-time dependence of the normalized magnetizations of (a) the carboxyl, (b) the methine, and (c) the methyl carbons under the condition $\Delta_{\text{eff}} = 2\nu_R$ satisfied between the carboxyl and the methyl carbons after saturation of the methyl carbon signal. The experiments were performed with the same parameters as described in the caption of Figure 3, excluding the initial magnetization for the methyl carbon. (Reproduced from Takegoshi et al.¹¹ with kind permission from Academic Press)

determined from spinning side bands observed at a low speed. The σ_{22} axis for N_I is assumed to be perpendicular to the peptide plane and the σ_{11} axis is along the N–C=O bond.¹⁶ For N_G , the σ_{33} direction is along the N_G – C_G^α bond direction and the σ_{11} axis is perpendicular to the N_G – C_G^α – C_G' plane.¹⁶ For the aliphatic carbons, it will be shown that the CSA interactions do not significantly affect simulated results. The ^{13}C and ^{15}N chemical shift parameters used for numerical simulations are collected in Table 1.

Figure 7 shows a ^{13}C COSY spectrum observed at $\nu_R = 17.5$ kHz under TPPM decoupling, presenting the connectivity between the observed eight signals (C_1 – C_8) splitted by the

Figure 5 Simulated mixing-time dependence of the methine carbon magnetization under the same conditions as described in the caption of Figure 4, excluding the isotropic chemical shift of the methine carbon. The assumed chemical shift relative to the methyl carbon is: (a) 0 Hz, (b) 500 Hz, (c) 1000 Hz, and (d) 2340 Hz

^{13}C – ^{13}C spin–spin couplings. From the connectivity and common knowledge of ^{13}C chemical shifts, all the signals can straightforwardly be assigned as $C_2 = C_G'$, $C_4 = C_G^\alpha$, $C_1 = C_I'$, $C_3 = C_I^\alpha$, $C_5 = C_I^\beta$, $C_6 = C_I^{\gamma 1}$, $C_7 = C_I^{\gamma 2}$, and $C_8 = C_I^\delta$. The observed isotropic chemical shifts are collected in Table 1.

Firstly, determination of the main-chain structure, which is described by dihedral angles conventionally named as ψ , ω , and ϕ (Figure 6), is discussed. ψ_G was determined by the selective-recoupling experiment of N_G and N_I . For the selective recoupling, an rf field with the intensity of 8300 Hz was applied on resonance to N_G , which satisfies a DQ condition under $\nu_R = 17.5$ kHz, and the recoupling-time dependence of the spin-locked magnetization of N_G was observed (Figure 8a). ψ_G was determined to be 180° from the root-mean-square deviation (RMSD) between the experimental data and the curves calculated for various ψ_G (Figure 8b). Let us examine to what extent the assumptions for the chemical shift tensors lead to error for determination of ψ_G . It was found that a deviation of 10° in the σ_{11} direction for N_I from the peptide bond direction to the N– C_α direction hardly changes the simulation curve. The deviation of 10° in the σ_{33} axis for N_G from the C_G^α – N_G bond direction does not change it either. The averages of the CSA parameters of the amide nitrogens¹⁶ in AcGlyGlyNH₂, AcGlyAlaNH₂, AcGlyTyrNH₂, and GlyGly·HCl gives $(\delta, \eta) = (103.2 \text{ ppm}, 0.22)$, which are similar to the observed ones, leads to the same ψ_G value of 180° as above. It should be pointed out, however, that changing the observed CSA parameters of N_I to those for the amide nitrogen in AcGlyTyrNH₂ $((\delta, \eta) = (96.4 \text{ ppm}, 0.26))$ or GlyGly·HCl $((\delta, \eta) = (101.0 \text{ ppm}, 0.02))$ ¹⁶ results in the best-fit values of $\psi_G = \pm 154$ or $\pm 159^\circ$, respectively. Such sensitivity of the recoupling-time dependence to the CSA parameters δ and η would be found particularly around $\psi = 180^\circ$ at which the ^{15}N – ^{15}N dipolar interaction becomes the weakest and thus insensitive to the dihedral angle. Nevertheless, the plot of $\Delta\chi^2$ shown in Figure 8(b) indicates that the 68% confidence interval ($\Delta\chi^2 < 1$) is still $\pm 10^\circ$. For a better precision, it is desirable to measure the CSA parameters of amide nitrogens and use them in the simulations for determining ψ .

Figure 6 Schematic representation of a glycyloisoleucine molecule. Typical values of the bond distances in Å and the bond angles in degrees are shown, which were used to simulate experimental results and construct the three dimensional structure of glycyloisoleucine. The glycine carbonyl and C_α carbons are labeled as C'_G and C_G^α , and the isoleucine carboxyl, C_α , C_β , $C_{\gamma 1}$, $C_{\gamma 2}$, C_δ carbons are as C'_I , C_I^α , C_I^β , $C_I^{\gamma 1}$, $C_I^{\gamma 2}$, and C_I^δ , respectively. The glycine amine and the isoleucine amide nitrogens are labeled as N_G and N_I , respectively, and the glycine carbonyl oxygen as O_G , and the two isoleucine carboxyl oxygens as O_I^1 and O_I^2 . The dihedral angles ϕ_I , ω_G , ψ_G , ψ_I , χ_{I1} , and χ_{I2} are also shown. (Reproduced from Nomura et al.¹³ with kind permission from Kluwer Academic Publishers)

^jDetermined by the sideband analysis of a low-speed MAS spectrum.

To determine ϕ_I , the selective recoupling experiment was done for C'_G and C'_I , where an rf field with an intensity of 8500 Hz was applied on resonance to the C'_I carbon while spinning with $\nu_R = 17.054$ kHz. Figure 9(a) shows the observed recoupling-time dependence of the magnetization of C'_I . If only the dipolar interaction between C'_G and C'_I contributes to the result, only the absolute value of the dihedral angle ϕ_I can be determined from this experiment. In the present case, however, the large CSAs of both carbons and the relative orientations between the CSA tensors, and some dipolar tensors significantly affect the experimental result. Hence, there may be a good chance of determining not only ϕ_I but also ψ_I with the signs. Since peptide planes take the *trans* configuration except for cyclic peptides or peptides with proline, ω_G was assumed to be 180° . Therefore,

the experimental curve was simulated, taking ϕ_I and ψ_I as adjustable parameters.

Figure 9(b) and (c) show the contour plots of RMSD between the experimental data and the curves calculated for various values of (ϕ_I, ψ_I) and $\Delta\chi^2$ around the global minimum of RMSD, respectively. These results provide the best-fit values of $(\phi_I, \psi_I) = (-76^\circ, 147^\circ)$ and the 68% confidence regions ($\Delta\chi^2 \sim 1$) of $(-1^\circ \sim 1^\circ)$ for ϕ_I and $(-9^\circ \sim 6^\circ)$ for ψ_I . Due to the imperfect selectivity of R2TR, C'_G , C_I^α , and C_I^β in addition to C'_G and C'_I had to be included to best simulate the recoupling curve. This resolves the degeneracy for (ϕ_I, ψ_I) and $(-\phi_I, -\psi_I)$ or $(180 - \phi_I, -\psi_I)$, which occurs if only C'_G and C'_I contribute to the recoupling curve. In fact, the $\Delta\chi^2$ value around $(\phi_I, \psi_I) = (76^\circ, 33^\circ)$ is relatively large (ca. 34). Hence, both ϕ_I and ψ_I could be uniquely determined. It should,

Figure 7 ^{13}C COSY spectrum of uniformly ^{13}C , ^{15}N -labeled glycyllsleucine. It was obtained under the spinning speed of 17.5 kHz and TPPM decoupling. (Reproduced from Nomura et al.¹³ with kind permission from Kluwer Academic Publishers)

however, be pointed out that ϕ_1 is precisely determined but ψ_1 is not. This is because the dipolar coupling directly contributes to the determination of ϕ_1 , but ψ_1 is obtained only through the relative orientation of the C'_1 CSA tensor to the other tensors. Therefore, the validity of the use of the CSA tensors assumed for C'_G and C'_1 in the above simulations should be examined.

First, as for C'_G , the experimental result was simulated using the CSA parameters and orientations determined for AcGlyGlyNH₂, AcGlyAlaNH₂, AcGlyTyrNH₂, and GlyGly·HCl.¹⁵ The best-fit values of (ϕ_1, ψ_1) do not deviate significantly for the four sets of parameters ($-71^\circ \sim -78^\circ$, $139^\circ \sim 148^\circ$). As for the tensor orientation of C'_1 , it was assumed that σ_{11} is parallel to the $\text{C}'_1\text{--C}'_1$ bond, while it may deviate from the bond direction by about 10° .¹⁴ It was found that the 10° deviation leads to $(\phi_1, \psi_1) = (-76^\circ, 138^\circ)$. For the CSA parameters (δ, η) , the values for glycine,¹⁷ L-alanine,¹⁸ L-serine,¹⁹ L-threonine,²⁰ and L-asparagine²¹ were used to find (ϕ_1, ψ_1) to be $(-75^\circ \sim -76^\circ, 137^\circ \sim 150^\circ)$.

These results show that the use of likely CSA tensors for C'_G and C'_1 in the simulations causes only a small error in the determination of ϕ_1 , but leads to a considerable error in ψ_1 . This is also because the ϕ_1 value is directly related to the distance, while the ψ_1 value is related mainly to the relative orientations of the CSA tensors, being more sensitive to them. To obtain a more precise value for ψ_1 , (δ, η) for C'_1 should be measured by some method.

The present result of the recoupling experiment for C'_G and C'_1 indicates that one dipolar recoupling experiment per amino acid residue is enough to determine dihedral angles (ψ, ω, ϕ) which provide the 3D backbone structure of a peptide. In the above, however, $\omega_G = 180^\circ$ was assumed, while in cyclic peptides or peptides with proline, ω_G may be 0° . Hence, the possibility of determining whether $\omega_G = 0^\circ$ or 180° was examined. The dotted line in Figure 9(a) shows

Figure 8 (a) Recoupling-time dependence of the normalized magnetization of N_G in 10% uniformly ^{13}C , ^{15}N -labeled glycyllsleucine. The dipolar recoupling experiment was carried out using the pulse sequence in Figure 2(a) under a R2TR condition ($\nu_{eI} + \nu_{eS} = \nu_R$) satisfied for N_G and N_I by applying a rf field with the intensity of 8300 Hz on resonance to N_G under MAS with $\nu_R = 17.5$ kHz. Experimental points are shown by circles. The standard deviation for each point is ca. ± 0.05 . The curves are calculated for the dihedral angle ψ_G of 180° . $T_{1\rho}$ was determined to be 70 ms by an off-R2TR experiment, and used to remove the relaxation effect from the dipolar recoupling data. (b) Dihedral angle (ψ_G) dependence of RMSD (---) between the experimental (Figure 8a) and simulated data and of $\Delta\chi^2$ (—). (Reproduced from Nomura et al.¹³ with kind permission from Kluwer Academic Publishers)

the curve simulated with $\omega_G = 0^\circ$ and the best-fit values of $(\phi_1, \psi_1) = (-86^\circ, 167^\circ)$, showing that it is difficult to determine the difference between the two possibilities $\omega_G = 0^\circ$ and $\omega_G = 180^\circ$ by this experiment. Therefore, another recoupling experiment was made for C'_G and C'_1 , by applying an rf field with an intensity of 2800 Hz on resonance to the C'_1 carbon which satisfies a DQ condition under spinning with $\nu_R = 17.03$ kHz. Figure 10 shows the recoupling-time dependence of the magnetization of C'_1 together with the simulated curves obtained for the two sets of $(\omega_G, \phi_1, \psi_1)$, namely, $(180^\circ, -76^\circ, 147^\circ)$ and $(0^\circ, -86^\circ, 167^\circ)$. Clearly, the former set reproduces the observation as expected. It indicates that even when one does not know whether $\omega = 0^\circ$ or 180° , one can determine the three dihedral angles (ψ, ω, ϕ) by two dipolar recoupling experiments per amino acid residue.

Figure 9 (a) Recoupling-time dependence of the normalized magnetization of C'_1 in 10% uniformly ^{13}C , ^{15}N -labeled glycylisoleucine. The dipolar recoupling experiment was carried out using the pulse sequence in Figure 2(a) under a R2TR condition ($\nu_{eI} + \nu_{eS} = \nu_R$) satisfied for C'_1 and C'_G by applying a rf field with the intensity of 8500 Hz on resonance to the C'_1 carbon under MAS with $\nu_R = 17.054$ kHz. Experimental points are shown by circles. The standard deviation for each point is ca. ± 0.03 . The solid line is the curve calculated for the dihedral angles $(\omega_G, \phi_1, \psi_1) = (180^\circ, -76^\circ, 147^\circ)$, whereas the dotted line for $(\omega_G, \phi_1, \psi_1) = (0^\circ, -86^\circ, 167^\circ)$. $T_{1\rho}$ was determined to be 500 ms for C'_1 in 10% uniformly ^{13}C , ^{15}N -labeled glycylisoleucine, and used to correct the experimental data. (b) The contour plot of RMSD between the experimental spectrum (Figure 5a) and the simulations for various sets of (ϕ_1, ψ_1) and $\omega_G = 180^\circ$. The global minimum is indicated by a dot. (c) Dihedral angles $(\phi_1$ and $\psi_1)$ dependence of $\Delta\chi^2$ for $\omega_G = 180^\circ$. (Reproduced from Nomura et al.¹³ with kind permission from Kluwer Academic Publishers)

As exemplified here, the recoupling-time behavior in a general $\text{sp}^2\text{--sp}^2$ ^{13}C spin pair depends not only on the internuclear distance, but also on the relative orientations between the CSA tensors and the dipolar vector as well as the CSA parameters. Owing to the dependence caused by CSA, the magnitudes of not only ϕ but also ψ can be determined. Moreover, a few more carbons also contribute to the experimental result due to the incomplete selectivity; however, it provides the benefit of being able to determine the signs of ϕ and ψ . While the contribution of CSA tensors and other spins makes the simulation troublesome and somewhat reduces the accuracy in determination of dihedral angles, it provides information which cannot easily be obtained by other means.

As described above, the dihedral angles for the main chain were determined. The dihedral angles for the side chain in the isoleucine residue can also be determined in a similar manner. However, since their chemical-shift values are very similar to each other and moreover the atomic positions are close to each other, selective recoupling of one of these pairs is indeed difficult. In this sense, the isoleucine residue is one of the most demanding ones for the present approach.

The χ_{II} angle was obtained by selective dipolar recoupling between C'_1 and $C_1^{\gamma 1}$, which was attained by applying a rf field with the intensity of 2000 Hz on resonance to the C'_1 carbon under MAS with $\nu_R = 17.46$ kHz. In the simulation, C_1^α , C_1^β , and C_1^δ besides C'_1 and $C_1^{\gamma 1}$ were included, and χ_{II} was determined to be 178° . The effect of the chemical shift tensors of C'_1 on the χ_{II} value were examined using the literature (δ, η) values of C' in L-alanine, L-serine, L-threonine, and L-asparagine, and it was found that the best-fit values of χ_{II} are virtually unaffected ($175^\circ \sim 178^\circ$). Also, changing the CSA parameters for $C_1^{\gamma 1}$ to those determined for the α -methylene carbon of *n*-eicosane²³ provides essentially the same value of $\chi_{\text{II}} = -176^\circ$.

As exemplified by the present case, in a general $\text{sp}^3\text{--sp}^2$ ^{13}C spin pair, possible variations of the parameters and orientations of their CSA tensors barely affects the recoupling-time dependence. Thus, likely CSA parameters (δ, η) and tensor orientations for both carbons may be used safely.

To determine the χ_{I2} angle in the same way as above, it is necessary to selectively recouple C_1^α and C_1^δ , or $C_1^{\gamma 2}$ and C_1^δ . Due to the spectral congestion, it is difficult to find a R2TR

Figure 10 Recoupling-time dependence of the normalized magnetization of C_1' in 10% uniformly $^{13}\text{C},^{15}\text{N}$ -labeled glycylisoleucine. The dipolar recoupling experiment was carried out using the pulse sequence in Figure 2(a) under a R2TR condition ($\nu_{eI} + \nu_{eS} = \nu_R$) satisfied for C_1' and C_1^α by applying a rf field with the intensity of 2800 Hz on resonance to the C_1' carbon under MAS with $\nu_R = 17.03$ kHz. Experimental points are shown by circles. The standard deviation for each point is ca. ± 0.04 . The solid line is the curve calculated for the dihedral angles $(\omega_G, \phi_1, \psi_1) = (180^\circ, -76^\circ, 147^\circ)$, whereas the dotted line for $(\omega_G, \phi_1, \psi_1) = (0^\circ, -86^\circ, 167^\circ)$. $T_{1\rho}$ was determined to be 500 ms for C_1' in 10% $^{13}\text{C},^{15}\text{N}$ -labeled glycylisoleucine, and used to correct the experimental data. (Reproduced from Nomura et al.¹³ with kind permission from Kluwer Academic Publishers)

condition suitable for these pairs. Therefore, a $C_1^\alpha-C_1^\beta/C_1^{\gamma 1}-C_1^\delta$ dipolar correlation 2D powder pattern was observed using the sequence shown in Figure 2(b). In this experiment, a 100% uniformly labeled sample was used for obtaining a high signal-to-noise ratio. The use of the undiluted sample is justified, because the dipolar interactions recoupled in the t_1 and t_2 periods are of directly bonded ones, and thus much stronger than the intermolecular dipolar interactions.

The spinning speed ν_R was set to 5110 Hz, satisfying the R^2 condition for C_1^δ and C_1^α . In the t_1 period, a DQ condition is matched for $C_1^{\gamma 1}$ and C_1^δ by applying an rf field with an intensity of 2540 Hz on resonance to C_1^δ . During the mixing time t_m , the magnetization of C_1^δ is selectively transferred to C_1^α by R^2 . In the t_2 period, a DQ condition is fulfilled for C_1^α and C_1^β by applying an rf field with an intensity of 1825 Hz on resonance to C_1^α . Figure 11(a) compares the experimental and the simulated 2D spectra, while Figure 11(b) shows the χ_{12} dependence of RMSD between the experimental and calculated 2D spectra. Even though the agreement is not excellent, the $\Delta\chi^2$ plot in Figure 11(b) shows that the 68% confidence interval is $\pm 5^\circ$, and χ_{12} was determined to be 160° . The sign of χ_{12} cannot be determined from this experiment. The dihedral angle $(C_1^{\gamma 2}-C_1^\beta-C_1^{\gamma 1}-C_1^\delta)$ was calculated to be 39° from $\chi_{12} = -160^\circ$, and to be 79° from $\chi_{12} = 160^\circ$; it suggests that the steric hindrance between the two methyl groups is smaller for the latter case. Therefore, the positive sign was preferred.

In the simulation, $C_1^{\gamma 2}$ in addition to C_1^α , C_1^β , $C_1^{\gamma 1}$, and C_1^δ were included, and a somewhat long $C_1^{\gamma 1}-C_1^\delta$ bond length of

Figure 11 (a) The 2D $C_1^\alpha-C_1^\delta/C_1^{\gamma 1}-C_1^\delta$ dipolar correlation spectrum for uniformly $^{13}\text{C},^{15}\text{N}$ -labeled glycylisoleucine. The experiment was performed using the pulse sequence in Figure 2(b). The spinning frequency ν_R is 5110 Hz. The ^{13}C rf-field intensities during the t_1 period, the mixing time, and the t_2 period are $\nu_1 = 2540$ (on resonance to the C_1^δ carbon), 0, and 1825 Hz (on resonance to the C_1^α carbon), respectively. (left) Experimental 2D spectrum. (right) Simulated 2D spectrum calculated for the $C_1^{\gamma 1}-C_1^\delta$ distance of 1.62 Å and the dihedral angle χ_{12} of 160° . The contour lines are plotted at 65, 77, and 88% of the maximum intensity. (b) Dihedral angle (χ_{12}) dependence of RMSD (---) between the experimental (Figure 11a) and simulated 2D dipolar correlation spectra and of $\Delta\chi^2$ (—). (Reproduced from Nomura et al.¹³ with kind permission from Kluwer Academic Publishers)

1.62 Å had to be assumed for the best fitting. This unusual bond length was attributed to a thermal vibration of C_1^δ . It is worthy to be noted that with the existence of molecular motion, dihedral angles cannot be correctly determined from distance measurements. However, in a theoretical study of vibrational effects,²⁴ it has been proved that the dipolar 2D powder patterns provide correct dihedral angles even under the presence of molecular vibrations as long as the asymmetry of the vibration is negligible. It is a common problem for various methods of structure determination that we must pay attention to the presence of local motion.

In these simulations, chemical shift anisotropies are not included, but it was found that even if likely chemical shift tensors are included, the spectrum does not appreciably change, under the MAS frequency of ~ 5 kHz. This is fortunate, because the CSA tensors of sp^3 carbons depend heavily on circumstances, so that it is very difficult to assume them appropriately for simulations. For a directly bonded sp^3-sp^3 ^{13}C spin pair, the effect of CSAs can indeed be neglected in comparison with the contribution of the dipolar coupling under MAS with a spinning speed a few times faster than $|\delta|$, according to

Figure 12 Three dimensional structure of glycy isoleucine. (a) NMR study; (b) X-ray crystallography. (Reproduced from Nomura et al.¹³ with kind permission from Kluwer Academic Publishers)

our simulations. On the other hand, for a nonbonded, namely weakly dipolar coupled sp^3-sp^3 ^{13}C spin pair, the effect of the CSAs becomes more important than for a directly bonded pair. Therefore, the CSA effect must be reduced for accurate determination of dihedral angles by using a sufficiently fast spinning speed. Then large ν_1 is needed for satisfying a DQ recoupling condition, so that selectivity is declined. Therefore, when some other sp^3 carbons exist close to the relevant carbons, the dipolar recoupling experiment (Figure 2a) does not work well, and the 2D dipolar correlation experiment (Figure 2b) is recommended.

Figure 12 shows the 3D structure constructed from the dihedral angles determined by the R2TR experiments, and that determined by X-ray crystallography. The dihedral angles determined by NMR and X-ray are $(\psi_G, \omega_G, \phi_I, \psi_I, \chi_{11}, \chi_{12}) = (180^\circ, 180^\circ, -76^\circ, 147^\circ, 178^\circ, 160^\circ)$ and $(165^\circ, 170^\circ, -70^\circ, 156^\circ, 178^\circ, 170^\circ)$, respectively. Although of course the result by NMR includes errors, we note that the structure determined by X-ray diffraction is not very accurate either. Nevertheless, both structures are in good agreement, indicating that the present approach is useful for structure determination. Further, the X-ray diffraction showed that the thermal vibration parameters of C_1^β are very large, agreeing with our observation by NMR.

5 CONCLUDING REMARKS

The complete 3D structure of a uniformly $^{13}C, ^{15}N$ -labeled Gly-Ile molecule were determined using the R2TR method. All the dihedral angles were individually determined by selectively recoupling some dipolar interactions between three or four-bonds distant spins or observing a dipolar correlation 2D powder pattern. Choosing three adjustable parameters ν_1 , ν_0 , and ν_R properly, it was possible to find a R2TR condition suitable for selective recoupling of the pair of spins concerned. Furthermore, it is not always necessary that all resonances are resolved; it is possible to monitor the recoupling-time dependence if only one of the pair of the spins concerned is resolved well from the others.

The present approach can be applied to determine the 3D structure of a small molecule and also the structure of a restricted region important to the biological function of a large system using a sample in which the region is uniformly or multiply labeled. So far quantitative structural information obtained by solid state NMR has been almost limited to a single internuclear distance or dihedral angle. The present approach increases the obtainable quantity of structural information in a single powder sample.

1 INTRODUCTION

In the beginning of the 1960s, NMR spectroscopists started to look for means to orient molecules with a particular goal in mind, i.e. to find a situation where the intermolecular direct dipolar couplings would average out whereas the corresponding intramolecular couplings would average to a nonzero value. Various methods were tried until, in 1963, Saupe and Englert¹ proposed that the sought-after properties can be reached by using liquid crystals as solvents.

The anisotropic orientational distribution of solute molecules in liquid crystals makes it possible to use the NMR observables (anisotropic couplings including both the direct dipole–dipole couplings and a contribution from the anisotropy of the indirect spin–spin coupling tensor, chemical shifts, and nuclear quadrupole splittings) for the determination of molecular structures, the anisotropies of nuclear shielding and spin–spin couplings, and quadrupole couplings for nuclei with spin ≥ 1 . In principle, the method is quite straightforward but in practice some complications may appear. In particular, the determination of molecular structures necessitates the introduction of the vibrational² and deformational^{3–5} corrections (see *Structure of Rigid Molecules Dissolved in Liquid Crystalline Solvents*). Since the anisotropic contribution of the spin–spin coupling tensor can only be separated from the experimental coupling when the direct dipole–dipole coupling is known, the corresponding effects have also to be considered here. To obtain reliable shielding anisotropies for protons and for nuclei with small anisotropy in general, various disturbing effects on the experimentally determined chemical shifts, such as local anisotropy due to solvent molecules, have to be taken into account.

A comprehensive review on the anisotropies of shielding and spin–spin coupling tensors determined using liquid crystalline solvents appeared in 1982.⁶ Since then, however, remarkable progress has taken place. This concerns spin–spin coupling anisotropy, in particular, where the inclusion of the deformational corrections leads to unambiguous, solvent independent results.

The NMR spectra observable from the spin- $\frac{1}{2}$ nuclei in molecules dissolved in liquid crystals resemble those in

isotropic liquids; relatively sharp, well resolved lines can be detected. Hence, analyses of spectra taken in the two phases are, in principle, similar (see *Liquid Crystalline Samples: Spectral Analysis*, and *Analysis of High-Resolution Solution State Spectra*). There are, however, also a few basic differences. Firstly, the anisotropic couplings between magnetically and chemically equivalent nuclei affect the structure of the spectrum. Thus, for example, the ^1H NMR spectrum of three methyl protons is a triplet and the six benzene protons give a spectrum very rich in resonance lines. Secondly, the dipole–dipole coupling constants are often large, of the order of kHz, and consequently the first-order approximation can usually be carried out only when the coupled nuclei are of different species.

2 LIQUID CRYSTALS

The liquid crystals most applicable in NMR spectroscopy are the thermotropic ones which have mesophases within certain temperature ranges.⁷ In a few cases, lyotropic liquid crystals have also been used. They are formed by mixing, for example, alkyl sulfates and the corresponding alcohols, sodium sulfate, and water.⁸

Thermotropic liquid crystals which are mainly used as solvents in NMR spectroscopy, can be classified into two main categories; nematic (N) and smectic (S). In the nematic phases, the molecules have only a short range positional order. However, if the liquid crystals consist of elongated molecules, as those used in the applications described in this context usually do, they tend to align with their long axes parallel to a common axis which defines the director (often called also the optic axis), $\mathbf{n}$, of the liquid crystal. The nematic phases are almost in all known cases uniaxial (rotational symmetry exists around the director) and apolar (the directions $\mathbf{n}$ and $-\mathbf{n}$ are equivalent). In the smectic phases the liquid crystal molecules possess long range order. A specific feature of smectic phases is the appearance of one-dimensional density waves or, as often called, layered structures. Smectic phases are divided into subgroups of which the smectic A phase (S_A) is the one used in the present applications. In this phase, the director coincides with the normal of the layer, and $\mathbf{n}$ and $-\mathbf{n}$ are equivalent. The structures of the nematic and smectic A phases are shown in Figure 1.

When a liquid crystalline sample is placed in an external magnetic field $\mathbf{B}$, the sample is magnetized so that the magnetization $\mathbf{M}$ is given by

$$M_\alpha = \mu_0^{-1} \chi_{\alpha\beta} B_\beta \quad (1)$$

Figure 1 Structures of thermotropic nematic (N) and smectic A (S_A) liquid crystalline phases. The direction of the director is shown by $\mathbf{n}$

2 ANISOTROPY OF SHIELDING AND COUPLING IN LIQUID CRYSTALLINE SOLUTIONS

where μ_0 is the permeability in vacuo and the $\chi_{\alpha\beta}$'s are elements of the diamagnetic (volume) susceptibility tensor, χ_m , which is diagonal in uniaxial phases.

The energy density, ρ_B , due to the magnetization $\mathbf{M}$ is:

$$\rho_B = - \int_0^B \mathbf{M} \cdot d\mathbf{B} = - \frac{B^2}{2\mu_0} \left[\chi_m + \frac{2}{3} \Delta\chi_m P_2(\cos \theta) \right] \quad (2)$$

where $\chi_m = \frac{1}{3} \text{Tr} \chi_m$ is the isotropic susceptibility, $\Delta\chi_m$ is the anisotropy of the susceptibility tensor, and $P_2(\cos \theta) = \frac{1}{2}(3 \cos^2 \theta - 1)$ is the second Legendre polynomial (θ being the angle between $\mathbf{B}$ and $\mathbf{n}$). Considering the condition of minimum energy density, one can conclude the following:

1. When $\Delta\chi_m$ is positive, ρ_B reaches a minimum with $P_2(\cos \theta) = 1$, i.e. the director is oriented parallel with the external magnetic field.
2. When $\Delta\chi_m$ is negative, ρ_B reaches a minimum with $P_2(\cos \theta) = -\frac{1}{2}$, i.e. when the director is oriented perpendicular to the external field.

Both types of thermotropic liquid crystals exist and have been used in studies of the properties of solute molecules. Furthermore, proper mixtures of liquid crystals with opposite signs of diamagnetic anisotropies have been utilized. (See *Liquid Crystals: Mixed Magnetic Susceptibility Solvents*.)

3 THE HAMILTONIAN OPERATOR AND OBSERVABLES

When considering the NMR spectra of spin- $\frac{1}{2}$ nuclei in molecules partially oriented in liquid crystals, the transition frequencies are dependent upon the nuclear shielding tensor, σ_i , the indirect spin-spin coupling tensor, $\mathbf{J}_{ij}$, and the direct dipole-dipole coupling tensor, $\mathbf{D}_{ij}$ (see *Liquid Crystals: General Considerations*). Then the total Hamiltonian operator is (in energy units):

$$\hat{\mathcal{H}} = -\hbar \sum_i \gamma_i \hat{\mathbf{I}}_i \cdot (\mathbf{1} - \sigma_i) \cdot \mathbf{B} + \hbar \sum_{i < j} \hat{\mathbf{I}}_i \cdot (\mathbf{J}_{ij} + \mathbf{D}_{ij}) \cdot \hat{\mathbf{I}}_j \quad (3)$$

where $\hbar$ is Planck's constant divided by 2π , γ_i is the magnetogyric ratio of nucleus i , and $\mathbf{1}$ is the unit tensor. On the basis of perturbation theory one can conclude that the terms of the Hamiltonian operator which do not commute with the total spin component, $\hat{I}_z$, in the direction of $\mathbf{B}$ (defined as the z direction of the laboratory frame) can be safely neglected. Furthermore, taking the time average of the observables over the anisotropic molecular tumbling, the operator shown in equation (3) can be approximated by:

$$\begin{aligned} \hat{\mathcal{H}} = & -\hbar \sum_i \gamma_i (1 - \sigma_i) B \hat{I}_{iz} \\ & + \hbar \sum_{i < j} J_{ij} \left[\hat{I}_{iz} \hat{I}_{jz} + \frac{1}{2} (\hat{I}_{i+} \hat{I}_{j-} + \hat{I}_{i-} \hat{I}_{j+}) \right] \\ & + \hbar \sum_{i < j} (2D_{ij} + J_{ij}^{\text{aniso}}) \left[\hat{I}_{iz} \hat{I}_{jz} - \frac{1}{4} (\hat{I}_{i+} \hat{I}_{j-} + \hat{I}_{i-} \hat{I}_{j+}) \right] \end{aligned} \quad (4)$$

In the operator shown in equation (4), the shielding is represented as

$$\begin{aligned} \sigma_i = \langle \sigma_{izz} \rangle &= \frac{1}{3} \sum_{\alpha} \sigma_{i\alpha\alpha} + \frac{2}{3} \left(\sum_{\alpha, \beta} S_{\alpha\beta} \sigma_{i\alpha\beta} \right) P_2(\cos \theta) \\ &= \sigma_i^{\text{iso}} + \sigma_i^{\text{aniso}} \end{aligned} \quad (5)$$

The isotropic spin-spin coupling constant, J_{ij} , and the anisotropic contribution, J_{ij}^{aniso} , are

$$J_{ij} = \frac{1}{3} \sum_{\alpha} J_{ij\alpha\alpha} \quad (6)$$

and

$$J_{ij}^{\text{aniso}} = \left(\frac{2}{3} \sum_{\alpha, \beta} S_{\alpha\beta} J_{ij\alpha\beta} \right) P_2(\cos \theta) \quad (7)$$

In equations (5)–(7), $\sigma_{i\alpha\beta}$ and $J_{ij\alpha\beta}$ are the elements of the shielding and spin-spin coupling tensor, respectively, in the molecule fixed coordinate system while the $S_{\alpha\beta}$ terms in turn, are the elements of the Saupe ordering tensor⁹ which are defined as

$$S_{\alpha\beta} = \frac{1}{2} \langle 3 \cos \theta_{\alpha n} \cos \theta_{\beta n} - \delta_{\alpha\beta} \rangle \quad (8)$$

where $\theta_{\alpha n}$ is the angle between the director $\mathbf{n}$ and the α axis of the coordinate system, the $\langle \rangle$ brackets indicate a time average, and $\delta_{\alpha\beta}$ is the Kronecker delta. The dipole-dipole coupling constant, D_{ij} , appearing in the operator shown in equation (4) is defined (when the correlation of the molecular reorientational and vibrational motions is neglected) as

$$D_{ij} = - \frac{\mu_0 \hbar \gamma_i \gamma_j}{8\pi^2 r_{ij}^3} S_{ij} \quad (9)$$

where r_{ij} is the internuclear distance, and

$$S_{ij} = \frac{1}{2} \langle 3 \cos^2 \theta_{ijB} - 1 \rangle \quad (10)$$

is called the order parameter (with respect to the external magnetic field) of the axis passing through i and j , and θ_{ijB} is the angle between the ij direction and the magnetic field. Since the order tensor is traceless and symmetric, it consists of five independent elements which are usually chosen as S_{cc} , ($S_{aa} - S_{bb}$), S_{ab} , S_{ac} , and S_{bc} (a , b and c are the axes of the molecule fixed coordinate system). Utilizing the coordinate transformation equation

$$S_{ij} = \sum_{\alpha, \beta} \cos \theta_{ij\alpha} \cos \theta_{ij\beta} S_{\alpha\beta} \quad (11)$$

S_{ij} can be written as:

$$\begin{aligned} S_{ij} = & \left[\frac{1}{2} S_{cc} (3 \cos^2 \theta_{ijc} - 1) + \frac{1}{2} (S_{aa} - S_{bb}) (\cos^2 \theta_{ija} - \cos^2 \theta_{ijb}) \right. \\ & + 2S_{ab} \cos^2 \theta_{ija} \cos^2 \theta_{ijb} + 2S_{ac} \cos^2 \theta_{ija} \cos^2 \theta_{ijc} \\ & \left. + 2S_{bc} \cos^2 \theta_{ijb} \cos^2 \theta_{ijc} \right] P_2(\cos \theta) \end{aligned} \quad (12)$$

The number of the independent elements of the order tensor can be reduced by taking into account molecular symmetry. The values of the order tensor elements are obtained from the dipole-dipole coupling constants provided that at least one internuclear distance is known.

4 SHIELDING ANISOTROPY

For a moment let us forget the complications that may occur particularly when determining small anisotropies of nuclear shieldings, and concentrate on the principles of how the shielding anisotropy is obtained from an NMR spectrum of a molecule partially oriented in a liquid crystal. Let us choose as an example a molecule possessing at least a

threefold symmetry axis, e.g. acetonitrile (CH_3CN). In such a case, the molecular orientation is completely determined by one order tensor element. Thus the experimental chemical shift, δ^{exp} , can be expressed in the form (note that δ increases to high frequency whereas σ increases to low frequency; for simplifying notations the subscript i will be omitted):

$$\begin{aligned}\delta^{\text{exp}} &= \delta^{\text{iso}} - \frac{2}{3} \left[\sigma_{zz} - \frac{1}{2}(\sigma_{xx} + \sigma_{yy}) \right] S P_2(\cos \theta) \\ &\equiv \delta^{\text{iso}} - \frac{2}{3} \Delta\sigma S P_2(\cos \theta)\end{aligned}\quad (13)$$

where $\sigma_{zz} - \frac{1}{2}(\sigma_{xx} + \sigma_{yy}) \equiv \Delta\sigma$ is the anisotropy of the shielding tensor [(x, y, z) is a molecule fixed coordinate system] and S is the order parameter of the molecular symmetry axis (which in the case of acetonitrile lies along the $-\text{C}\equiv\text{N}$ direction). Equation (13) contains two unknown parameters δ^{iso} and $\Delta\sigma$; the order parameter S is obtained from the experimental dipole-dipole couplings [defined in equation (9)] which do not contain an anisotropic contribution, J_{ij}^{aniso} , and are corrected for harmonic vibrations and preferably also for deformational contributions. Usually couplings of the type D_{HX} with ^1H as a coupling partner (D_{HH} in CH_3CN) are a safe choice.

The shielding anisotropy can be determined by changing either S or $P_2(\cos \theta)$. There exist several possibilities for both. They are described below.

4.1 Use of Isotropic–Nematic Phase Transitions

In this method, $\delta^{\text{iso}} = \delta^{\text{exp}}(\text{isotropic})$ is determined in the liquid crystal heated to the isotropic state (when $S \equiv 0$) and assumed not to be affected by the change of phase. Then the sample is cooled to the nematic state and $\delta^{\text{exp}}(\text{nem.})$ is measured. Consequently,

$$\Delta\sigma = -\frac{3}{2} \left[\frac{\delta^{\text{exp}}(\text{nem.}) - \delta^{\text{exp}}(\text{isotropic})}{S P_2(\cos \theta)} \right] \quad (14)$$

4.2 Gradient Method

One disadvantage of the previous method is that the experiments have to be carried out at two different phases, isotropic and nematic. This can be avoided by working exclusively in a nematic or smectic phase and changing the molecular degree of order, i.e. the order parameter S . This is achieved by changing the temperature or concentration of the sample. When δ^{exp} is expressed graphically as a function of $S P_2(\cos \theta)$, the slope of the resulting straight line gives $\Delta\sigma$ and the intercept δ^{iso} .

4.3 Use of Smectic Phases

The smectic A phases of thermotropic liquid crystals often possess the property that once oriented in a magnetic field they keep the orientation for a long time. This makes it possible to change in a very straightforward way the angle between the director $\mathbf{n}$ and the magnetic field $\mathbf{B}$, i.e. the factor $P_2(\cos \theta)$ in equation (13), while S remains unchanged.¹⁰ The

shielding anisotropy is then obtained without changing solvent properties.

When the liquid crystal is heated to the isotropic state and then cooled in the magnetic field to the smectic state, the director orients (when $\Delta\chi_m > 0$) along the magnetic field and $\theta = 0$. Thus

$$\delta^{\text{exp}}(0) = \delta^{\text{iso}} - \frac{2}{3} \Delta\sigma S \quad (15)$$

The rotation of the sample (in a conventional electromagnet) around the tube axis by 90° [generally, the rotation angle is obtained from the ratio of the dipolar couplings: $D_{ij}(\theta)/D_{ij}(0) = P_2(\cos \theta)$] gives:

$$\delta^{\text{exp}}(90) = \delta^{\text{iso}} + \frac{1}{3} \Delta\sigma S \quad (16)$$

and consequently,

$$\Delta\sigma = \frac{\delta^{\text{exp}}(90) - \delta^{\text{exp}}(0)}{S} \quad (17)$$

In the smectic phases the degree of solute molecular orientation is usually high, when both S and the chemical shift difference [nominator in equation (17)] are large, leading to a good relative precision in $\Delta\sigma$. Figure 2, which shows the ^{199}Hg NMR spectrum of dimethylmercury ($\text{CH}_3)_2\text{Hg}$ at the orientation described above, illustrates the method.

4.4 Use of Mixtures of Thermotropic Nematic Liquid Crystals

4.4.1 Liquid Crystals with Opposite Diamagnetic Anisotropy

This method, called NEMIX, is comparable with the one described in Section 4.3. When two thermotropic nematic liquid crystals possessing opposite anisotropies of diamagnetic susceptibility, $\Delta\chi_m$, are mixed at a certain critical concentration ratio ($\Delta\chi_m$ of the critical mixture is equal to 0), the 90°

Figure 2 ^{199}Hg NMR spectrum of dimethylmercury $[(\text{CH}_3)_2\text{Hg}]$ in the smectic A phase of HAB: 0° , director parallel with the external magnetic field, 90° , director perpendicular to the external magnetic field. (Reproduced with permission of Heyden & Sons from J. Jokisaari and P. Diehl²⁶)

Figure 3 The experimental chemical shift, δ_F^{exp} , of the ^{19}F nucleus and the order parameter of the C_3 symmetry axis, S , for methyl fluoride (CH_3F) as a function of the liquid crystal composition in mixtures of ZLI 1167 and EBBA. The mixtures used in the NEMIX and ENEMIX methods are indicated by N and E, respectively

rotation of the liquid crystal director is achieved by changing the sign of $\Delta\chi_m$ with the aid of a slight temperature change or a small temperature gradient over the sample volume (see *Liquid Crystals: Mixed Magnetic Susceptibility Solvents*). In the latter case, the NMR spectra corresponding to the two director orientations can be detected simultaneously.^{11,12} The shielding anisotropy can be calculated from equation (17). Figure 3 shows how the method works.

4.4.2 Liquid Crystals with Opposite Deformational Effects on Molecular Structure

The anisotropic forces that cause the orientation of solute molecules at the same time deform their structure leading to the solvent dependence of structure. It has appeared that ^{13}C -enriched methane ($^{13}\text{CH}_4$) is a convenient and practical reference, not only for chemical shifts but also for structural deformations. It has been found that in certain mixtures of thermotropic liquid crystals the methane molecule is not deformed.¹³ The components of the mixture may be selected so that they possess opposite diamagnetic anisotropies and, consequently, parallel and perpendicular orientations of the director with respect to the external magnetic field can be produced in a similar way to that discussed above. Figure 3 also demonstrates this method, which is called ENEMIX. In contrast to the NEMIX method and the method based on the utilization of smectic liquid crystals, the ratio of the S parameters corresponding to the two director orientations may not exactly equal -2 , whence

$$\Delta\sigma = -\frac{3}{2} \left[\frac{\delta^{\text{exp}}(0) - \delta^{\text{exp}}(90)}{S(0) - S(90)} \right] \quad (18)$$

4.5 Use of Sample Spinning

4.5.1 Sample Tube Axis Perpendicular to the Magnetic Field

As discussed above, the liquid crystals director orients either along the external magnetic field or perpendicular to it depending upon the sign of the diamagnetic anisotropy. In a conventional electromagnet, the director orients perpendicular to the tube axis (when $\Delta\chi_m > 0$; if $\Delta\chi_m < 0$ the director orients along the tube axis and no change in the orientation can be achieved by spinning the sample tube). When the sample is spinning around the tube axis the liquid crystal experiences a viscous torque

$$N_v = \lambda_1 \Omega \quad (19)$$

where Ω is the angular speed and λ_1 a coefficient proportional to the viscosity of the solution. The magnetic torque opposes the viscous torque, and in equilibrium $N_B = N_v$. Thus the angle θ_0 between the magnetic field and the director is determined by

$$\sin 2\theta_0 = -\frac{2\mu_0\lambda_1}{B^2\Delta\chi_m} \Omega \quad (20)$$

The value of $SP_2(\cos \theta_0)$ can be determined from the dipolar coupling constants and the shielding anisotropy calculated as in the previous method. On the other hand, θ_0 can be varied by varying the angular speed Ω . There is, however, an upper limit for Ω , the so-called critical speed, $\Omega_c = -B^2\Delta\chi_m/2\mu_0\lambda_1$, above which no equilibrium state can be reached but the director rotates with the tube. When the experimental chemical shift is plotted as a function of $SP_2(\cos \theta_0)$, the shielding

anisotropy is obtained from the slope of the resulting straight line.

4.5.2 Variable Angle Spinning

Let us consider a general case where the spinning axis of a sample tube forms an angle β with the magnetic field. Transforming the susceptibility tensor into the principal axis system rotating around the magnetic field direction and taking a time average,¹⁴ the magnetic energy density can be represented in the form

$$\langle \rho_B \rangle = -\frac{B^2}{2\mu_0} \left[\chi_m + \frac{2}{3} \Delta\chi_m P_2(\cos \beta) P_2(\cos \delta) \right] \quad (21)$$

where δ is the angle between the spinning axis and the liquid crystal director. From the condition of minimum energy density, one can conclude the following: (a) when $\Delta\chi_m > 0$ and $0 \leq \beta < \beta_m$ (β_m is the magic angle, 54.7°), the liquid crystal director orients parallel with the spinning axis, i.e. the angle between the director and the magnetic field equals β ; (b) when $\Delta\chi_m > 0$ and $\beta_m < \beta \leq \pi/2$, the directors are equally distributed in the plane perpendicular to the spinning axis; (c) when $\Delta\chi_m < 0$ and $0 \leq \beta < \beta_m$, the situation is similar to (b); and (d) when $\Delta\chi_m < 0$ and $\beta_m < \beta \leq \pi/2$, the situation is similar to (a).

The slope of the resulting straight line obtained by plotting the experimental chemical shift as a function of $SP_2(\cos \beta)$, or as a function of a dipolar coupling constant as shown in Figure 4, gives the shielding anisotropy.

4.6 Examples and Reliability of Results

4.6.1 Molecules Whose Orientation Can Be Described by One Order Parameter

Tables (1)-(3) show $\Delta\sigma$ values determined by applying various liquid crystals and methods described above. The examples are chosen so that they cover a wide range of values, and consequently yield the weaknesses on the one hand and the reliability on the other hand of liquid crystal NMR spectroscopy as applied to the determination of shielding anisotropies. Table 1 lists the proton shielding anisotropy values measured for acetonitrile (CH_3CN). As can be seen, they vary over a relatively wide range, and both positive and negative values have been reported. The $\Delta\sigma_H$ value seems to depend upon the method used, liquid crystal solvent, and reference method and substance. This is due to the fact that the measured shielding is affected by three different anisotropic contributions:

$$\sigma^{\text{exp}} = \sigma^{\text{mol}} + \sigma^{\text{local}} + \sigma^{\text{bulk}} \quad (22)$$

where σ^{mol} (the quantity of interest) arises from the electron distribution in the molecule, σ^{local} (the local effect) from the nearest neighbor molecules, and σ^{bulk} (the bulk effect) from the other parts of the sample. The greatest problem is caused by the local effects; obviously the solute and reference molecules do not probe exactly the same local fields, leading to an erroneous $\Delta\sigma$. Local effects in a smectic liquid crystal, and in mixtures of thermotropic nematic liquid crystals with opposite diamagnetic anisotropies, have been studied by using globular solutes (which do not orient in liquid crystals, i.e. $S = 0$) and found to be from -0.2 to -0.5 ppm for protons.¹⁵⁻¹⁷ These

Figure 4 Plot of δ^{exp} for the ^1H nucleus (referenced to internal TMS) as a function of D_{HH} for methyl iodide (CH_3I) in three liquid crystals: phase 4 ($\square$); ZLI 1167 (39.1%)/phase 4 (60.9%) ($\bullet$); and ZLI 1167 (57.6%)/phase 4 (42.4%) ($\times$). The data were produced on a VAS system by varying the angle between the spinning axis and the external magnetic field. The slope, κ , of the straight line yields the proton shielding anisotropy $\Delta\sigma_H = (3/4) (K_{\text{HH}}/r_{\text{HH}}^3) \kappa$, where $K_{\text{HH}} = \mu_0 \hbar \gamma_H^2 / 8\pi^2$. (Reproduced with permission of Academic Press from T. Väänänen, J. Jokisaari, and M. Seläntaus³³). Note: the δ scale is opposite to the one used in the present text

experiments and the earlier ones^{18,19} mean that the anisotropic contribution of the local effects may be of the same magnitude as σ^{aniso} for protons, but also for other nuclei if their shielding anisotropy is not very large.

The first column of Table 2 shows that the shielding anisotropy of the methyl carbon, $\Delta\sigma_{\text{CH}_3}$ in acetonitrile, being of the order of 20 ppm, also depends markedly on the applied experimental method and liquid crystal solvent. On the contrary, the shielding anisotropies measured for the $-\text{C}\equiv\text{N}$ carbon, $\Delta\sigma_{\text{CN}}$, in acetonitrile as well as those for the ^{199}Hg nucleus in dimethylmercury $[(\text{CH}_3)_2\text{Hg}]$ (see Table 3) are virtually insensitive to all these factors. The small scatter arises from the internuclear distance chosen as a basis in calculating the order parameter S and from whether vibrational corrections are taken into account or not.

The experiments carried out until now and comparisons made with the values produced by other techniques or theoretical calculations provide strong support for the modified ENEMIX method giving the most reliable estimates for small $\Delta\sigma$ s.²¹

4.6.2 Molecules Whose Orientation Can Be Described by Two Order Parameters

In cases where molecules possess two perpendicular planes of symmetry as, for example, monosubstituted benzenes and heteroatomic five-membered rings, the experimental chemical shift can be represented in the form:

$$\delta^{\text{exp}} = \delta^{\text{iso}} - \frac{2}{3} \left\{ S_{zz} \left[\sigma_{zz} - \frac{1}{2} (\sigma_{xx} + \sigma_{yy}) \right] + \frac{1}{2} (S_{xx} - S_{yy}) (\sigma_{xx} - \sigma_{yy}) \right\} P_2(\cos \theta) \quad (23)$$

^bIGLO method with two different basis sets. Large basis set results on the right.

The shielding anisotropy, $\Delta\sigma = \sigma_{zz} - \frac{1}{2}(\sigma_{xx} + \sigma_{yy})$, and the difference $(\sigma_{xx} - \sigma_{yy})$ are obtained separately only if the ratio $(S_{xx} - S_{yy})/S_{zz}$ can be varied. Consequently, none of the methods described above which are based on the change of direction of the liquid crystal director with respect to the external magnetic field, i.e. the variation of the $P_2(\cos \theta)$ factor, is applicable here. The variation of the ratio $(S_{xx} - S_{yy})/S_{zz}$ may be produced by changing the sample temperature or by using different liquid crystal solvents. Then one has to assume that the shielding tensor elements are not affected by the experimental conditions.

The determination of the ¹³C shielding anisotropies in molecules which are large in the liquid crystal NMR scale (when the number of magnetic nuclei increases, the NMR spectrum of an oriented molecule becomes very complex; in practice the upper limit for the number of active, interacting nuclei is 10–12), and contain several carbon atoms and ¹³C in natural abundance, is usually at least very cumbersome if not impossible from the proton coupled spectra. Therefore, a method has been proposed which uses a spin echo sequence $[90^\circ - \tau - 180^\circ - 2\tau - 180^\circ - \tau - \text{acquisition}]$ and phase-alternated broadband decoupling.³⁰ The echo sequence cancels the possible overlap of the solute signals by the solvent signals.

Figure 5 The ^{125}Te NMR spectrum of tellurophene ($\text{C}_4\text{H}_4\text{Te}$) in (a) ZLI 1167 (58%)/phase 4(42%), (b) EBBA and (c) ZLI 1167. (Reproduced with permission of Taylor & Francis from J. Jokisaari and T. Väänänen³¹)

The ^{13}C NMR spectrum yields the chemical shifts whereas the order parameters appearing in equation (23) are obtained from the ^1H spectrum.

The NMR spectroscopy of solute molecules in liquid crystals has not been applied very much to the investigations of shielding anisotropies of the so-called heavy nuclei. Most of the studies deal with the ^1H , ^{13}C , ^{19}F , and ^{31}P nuclei, and highly symmetrical molecules.⁶ This is somewhat surprising because the method is best when the shielding anisotropy is fairly large. There has been, however, some work carried out for ^{111}Cd , ^{113}Cd , and ^{199}Hg in molecules with C_3 symmetry, and one work for the ^{125}Te nucleus in a C_{2v} symmetric molecule, tellurophene ($\text{C}_4\text{H}_4\text{Te}$).³¹ The ^{125}Te NMR spectra of tellurophene in three liquid crystals are shown in Figure 5.

Equation (23) can be rewritten in the form

$$-\frac{3}{2} \left[\frac{\delta^{\text{exp}} - \delta^{\text{iso}}}{S_{zz}} \right] = \left[\sigma_{zz} - \frac{1}{2}(\sigma_{xx} + \sigma_{yy}) \right] + \frac{\sigma_{xx} - \sigma_{yy}}{2} \frac{S_{xx} - S_{yy}}{S_{zz}} \quad (24)$$

Table 4 The Results of the ^{125}Te NMR Study of Tellurophene Dissolved in three Liquid Crystals.³¹ The Signs of δ^{exp} and δ^{iso} are Opposite to those in the Original Paper due to the Different Definition of the δ scale

Liquid crystal	δ^{exp} (ppm)	δ^{iso} (ppm) ^a	$(S_{xx} - S_{yy})/S_{zz}$ ^b	S_{zz} ^{b,c}
EBBA	2.50	-33.55	0.5033	0.0363
ZLI 1167/phase 4	48.51	-34.83	1.7478	0.0953
ZLI 1167	-85.02	-35.60	1.9992	-0.0592

The intercept of the straight line obtained by plotting the left hand side of equation (24) as a function of $(S_{xx} - S_{yy})/S_{zz}$ yields $[\sigma_{zz} - \frac{1}{2}(\sigma_{xx} + \sigma_{yy})]$ whereas the slope gives $(\sigma_{xx} - \sigma_{yy})$. The results derived for ^{125}Te in tellurophene are collected in Table 4.

5 SPIN-SPIN COUPLING ANISOTROPY

The determination of reliable anisotropies, ΔJ_{ij} , of the spin-spin coupling tensors using NMR spectroscopy of molecules dissolved in liquid crystals may be a fairly difficult task. This is due to the fact that the experimental couplings, D_{ij}^{exp} , are dominated by the direct dipole-dipole coupling tensor elements, and moreover, in real molecules the dipole-dipole as well as spin-spin coupling tensors are averages over intramolecular motions. However, when performing proper analyses of data (sets of D_{ij}^{exp} values) preferably (often necessarily) produced in many liquid crystal solvents, most reliable and accurate ΔJ_{ij} values can be determined.

5.1 Quantitative Determination of J Anisotropy

The experimentally available couplings D_{ij}^{exp} can be expressed as a sum of several contributions (*Structure of Rigid Molecules Dissolved in Liquid Crystalline Solvents*):

$$D_{ij}^{\text{exp}} = D_{ij}^{\text{e}} + D_{ij}^{\text{ah}} + D_{ij}^{\text{h}} + D_{ij}^{\text{d}} + \frac{1}{2} J_{ij}^{\text{aniso}} \quad (25)$$

In equation (25), the first four terms on the right-hand side constitute the direct dipolar part of the coupling: D_{ij}^{e} is the dipole-dipole coupling corresponding to the equilibrium structure of the molecule; D_{ij}^{aff} is the contribution from the anharmonicity of the vibrational potential (the sum of these terms $D_{ij}^{\text{e}} + D_{ij}^{\text{ah}} = D_{ij}^{\alpha}$ is the dipole-dipole coupling corresponding to the so-called r_{α} structure of the molecule; the anharmonic force constants are often not available and thus only the r_{α} structure can be determined); D_{ij}^{h} is the contribution from the harmonic vibrations; and D_{ij}^{d} (the so-called deformational contribution which is responsible for the solvent dependence of structure) from the correlation between

$$\Delta\sigma = \sigma_{zz} - \frac{1}{2}(\sigma_{xx} + \sigma_{yy}) = -1569 \pm 21 \text{ ppm}$$

$$\sigma_{xx} - \sigma_{yy} = 307 \pm 26 \text{ ppm}$$

^aObtained from a sample heated to isotropic state.

^bDetermined from the ^1H - ^{125}Te dipolar couplings by assuming the corresponding J^{aniso} to be negligible.

^cWith respect to the external magnetic field.

vibrational and reorientational motions (time averages of S_{ij} and r_{ij}^{-3} appearing in the definition of the dipole–dipole coupling, equation (9), cannot be taken independently).

In order to get a reliable value for J_{ij}^{aniso} (which is normally small and in many cases comparable in magnitude with the vibrational and deformational correction terms), the molecular structure should be determined as completely as possible with the aid of the D_{ij}^{exp} values. This necessarily means a full analysis of data taking into account the interactions (the anisotropic forces that tend to orient molecules) between the solute and solvent molecules. In such an analysis the number of unknown parameters often exceeds the number of D_{ij}^{exp} values obtainable from one experiment, i.e. the problem becomes underdetermined. This increasing number of parameters is a consequence of the deformational effects. For example, in order to be able to calculate deformational corrections to J^{aniso} , one should know the derivatives of the spin–spin coupling tensor with respect to the vibrational normal coordinates. These are not available, and consequently must be used as adjustable parameters.³² The problem of underdetermination can, however, be overcome by carrying out experiments in several liquid crystalline solvents.

Another uncertainty in the determination of J_{ij}^{aniso} may appear in cases of spin systems consisting of different nuclear species, for instance I and S spins. Thus, the NMR spectrum yields only the sum $|2D_{is}^{\text{exp}} + J_{is}|$. If the spin–spin coupling constant, J_{is} , cannot be determined under the same experimental conditions (the same solvent, temperature, concentration, etc.) as the sum, an additional uncertainty is introduced into D_{is}^{exp} , and consequently, also into J_{is}^{aniso} . In principle, J_{is} can be determined in liquid crystalline phases by performing, for instance, VAS (Variable Angle Spinning) experiments.³³

Let us consider the determination of the anisotropy of the ^{13}C – ^{19}F spin–spin coupling in the methyl fluoride (CH_3F) molecule. Due to the C_3 symmetry of the molecule, its orientation can be described by one order parameter, S , of the symmetry axis. Then the anisotropic contribution to the experimental coupling $D_{\text{CF}}^{\text{exp}}$ can be expressed in the form:

$$J_{\text{CF}}^{\text{aniso}} = \frac{2}{3} \Delta J_{\text{CF}} S P_2(\cos \theta) \quad (26)$$

where $\Delta J_{\text{CF}} = J_{\text{CFzz}} - \frac{1}{2}(J_{\text{CFxx}} + J_{\text{CFyy}})$ is the anisotropy of the coupling tensor $\mathbf{J}_{\text{CF}}$. When the experimental dipolar couplings are corrected for harmonic vibrations but the deformational corrections are neglected, ΔJ_{CF} appears to be solvent dependent to a very great extent, as shown in Table 5. This large scatter of results is removed when all the dipolar couplings and $J_{\text{CF}}^{\text{aniso}}$ are corrected for deformational effects and a joint analysis of nine experiments (44 couplings, $D_{\text{CF}}^{\text{exp}}$ in one liquid crystal could not be obtained, and 23 parameters) is carried out. This analysis results in $\Delta J_{\text{CF}} = 404 \pm 31$ Hz. The relative anisotropy, $\Delta J_{\text{CF}}/J_{\text{CF}}$, is -2.50 ± 0.20 (J_{CF} appears to be slightly dependent upon the liquid crystal solvent, its average value is -161.43 Hz) and should be compared with -2.70 obtained by Hartree–Fock theory (ab initio) and by a semiempirical finite perturbation method at the INDO MO level of approximation.³⁴ The first-order polarization propagator approach has led to the ΔJ_{CF} value of 296.41 Hz.³⁵ Consequently, the experimental results of a joint analysis and the theoretical results are in fair agreement.

Reinforcement for the workability of the method is provided by the studies on acetonitrile (CH_3CN) and methyl isocyanide

Table 5 The Anisotropy ΔJ_{CF} of the ^{13}C – ^{19}F Spin–Spin Coupling Tensor for Methyl Fluoride ($^{13}\text{CH}_3\text{F}$) in Various Liquid Crystals. The Dipolar Couplings are Corrected for Harmonic Vibrations but not for Deformational Effects. The Result of the Joint Analysis (which takes into account also the Deformational Effects) of Nine Sets of D_{ij}^{exp} Values (44 Couplings and 23 Parameters) is also given for Comparison³²

(CH_3NC). Table 6 clearly shows that when the harmonic vibrational and deformational effects are taken into account in the experimental dipolar couplings, the ΔJ values are in nice accord with the theoretical ones.

5.2 Qualitative Revelation of J Anisotropy

Molecular symmetry can place very restrictive conditions for the ratios of dipolar coupling constants. Consequently, this can be used to reveal whether D^{exp} includes a contribution from J^{aniso} or not. If the examination of the ratios $D_{ij}^{\text{exp}}/D_{kl}^{\text{exp}}$ shows that they differ from the corresponding ratios of direct dipolar couplings ($D^{\text{dir}} = D^{\text{exp}} - \frac{1}{2}J^{\text{aniso}} = D^e + D^{\text{ah}} + D^{\text{h}} + D^{\text{d}}$, see equation (26)), they (or at least some of them) may be affected by J^{aniso} .

Benzene is a good example of a molecule in which symmetry completely fixes the ratios of the dipolar couplings. The order parameter of each ij direction equals $-\frac{1}{2}S$ (S is the order parameter of the sixfold symmetry axis) and consequently the following equation is valid:

$$\frac{D_{ij}^{\text{dir}}}{D_{kl}^{\text{dir}}} = \frac{\gamma_i \gamma_j}{\gamma_k \gamma_l} \left(\frac{r_{kl}}{r_{ij}} \right)^3 \quad (27)$$

It follows from the hexagonal symmetry of benzene that $r_m = \sqrt{3}r_o$ and $r_p = 2r_o$ ($o = \text{ortho}$, $m = \text{meta}$, $p = \text{para}$). Thus for the nuclei of same isotopic species, $D_o/D_m/D_p = 1 : \sqrt{3}/9 : 1/8 \sim 1 : 0.1925 : 0.1250$. It has been found that the ^1H – ^1H couplings in benzene indeed fulfil these ratios (in particular, when the experimental couplings are corrected for harmonic vibrational and deformational effects) and thus the $J_{\text{HH}}^{\text{aniso}}$ values are obviously negligible.⁴ In contrast, remarkable deviations have been detected for the ^{13}C – ^{13}C couplings (corrected for harmonic vibrations).³⁹

Equation (27) is not only valid for benzene but more generally. Thus, if S_{ij} for the nuclei i and j is the same as S_{kl} for the nuclei k and l , in other words the axes passing through

1 INTRODUCTION

The concept that nuclear spin–spin coupling might occur by through-space as well as through-bond interactions was introduced many years ago to account for the observations that certain atoms which are crowded against one another intramolecularly exhibit unusually large coupling constants as measured by NMR spectroscopy.^{1,2} The early work on through-space coupling was reviewed in 1975,³ and a review of various theoretical treatments of the phenomenon appeared in 1985.⁴

This article is concerned only with spin–spin coupling between pairs of magnetic nuclei in molecules that are freely tumbling in fluid solution such that direct ‘through-space’ dipole–dipole interactions between the two nuclei are averaged to zero. The observed coupling arises instead from intramolecular Fermi contact and Hund interactions involving the nuclear spins and the spins of electrons in the molecule. Fermi contact interaction between a magnetic nucleus and an electron requires these two particles to be essentially coincident in space, which is possible only if the electron is in an orbital with s character at that nucleus. The system is lower in energy if the electron and the nucleus with which it is in intimate contact have antiparallel spins. Hund interactions are operative between two electrons that are contained in two different orbitals that have some spatial overlap of their electron densities. When an electron from one of the orbitals inhabits the same region of space as an electron from the other orbital the system has a lower energy if the two electrons have parallel spins.

The phenomenon of through-space coupling has been reported for spatially proximate pairs of nuclei of various types, including ^{19}F – ^{19}F , ^1H – ^{19}F , ^{13}C – ^{19}F , ^1H – ^1H , ^{15}N – ^{19}F ,

Figure 1 Examples of through-space coupling

^{31}P – ^{19}F , and ^{13}C – ^{31}P systems. Some examples are shown in Figure 1.

Initially the proposals for the existence of a special through-space mode of coupling were greeted with some skepticism. For example, there seemed no convincing way to rule out the alternative possibility that the large coupling

constants observed for various molecules related to 1,8-difluoronaphthalene (**1**) result instead from peculiarly effective through-bond interactions in the U-shaped array of the four relevant bonds in the FCCCCF fragment. The early history of the study of the through-space coupling phenomenon was marked by attempts to dispel this skepticism. One compelling piece of evidence in this context was the report that several disubstituted 4,5-difluorophenanthrenes, in which the shortest through-bond pathway is one bond longer than that in the 1,8-difluoronaphthalene system but the intramolecular crowding between the two fluorine atoms is greater, exhibited astonishingly large coupling constants in the range 167–170 Hz;¹⁸ a value of 174 Hz was reported subsequently for the mono-substituted derivative (**2**).^{7,8} Another convincing piece of evidence was provided by a study of the analog of the enzyme dihydrofolate reductase in which the four tryptophan residues in the native enzyme had been replaced biosynthetically by 6-fluorotryptophan residues.¹⁹ It happens that the tertiary structure of this enzyme places two of these four tryptophan (or fluorotryptophan) residues, namely residues 133 and 158, in van der Waals contact with one another. The ¹⁹F NMR spectrum of a fluorine-substituted enzyme shows four fluorine signals, two singlets and two doublets with a coupling constant of 17 Hz.¹⁹ There is no reasonable way to attribute this F–F coupling to through-bond interactions, because the shortest through-bond pathway connecting the two spatially proximate fluorines is 89 bonds long!

Both through-space and through-bond interactions contribute to the observed coupling in molecules such as those shown in Figure 1. That is, the experimentally measured coupling constant J can be expressed as a sum of through-space and through-bond components, J^{TS} and J^{TB} , respectively:

$$J = J^{\text{TS}} + J^{\text{TB}} \quad (1)$$

Perhaps the central unsolved problem in the quest for a precise understanding of the dependence of through-space coupling on molecular structure is the lack of a reliable means of dissecting the observed coupling into its through-space and through-bond components. In a few atypical cases, such as the F–F coupling in the enzyme system discussed above, this dissection is easily made because it is clear that the through-bond component is zero. Although the experimentally determined values of $J(\text{FF})$ for molecules such as (**1**)–(**3**) are sufficiently large that it seems safe to conclude qualitatively that the through-space mode of coupling plays a dominant role, the actual magnitudes of the through-space components cannot be assessed quantitatively in any of these systems because there is no reliable way to determine experimentally the magnitudes of the accompanying through-bond contributions. At this time it appears that theoretical calculations offer the best, or perhaps the only, hope for evaluating the relative importance of the through-space and through-bond modes of coupling in particular molecules. Some computational methods currently under development appear promising in this context.^{4,20,21}

In the early days of the study of through-space F–F coupling a conceptual view of the mechanism of this type of coupling was put forward by one of us based on the mixing of lone-pair orbitals through overlap interactions.²² In the next section we present a modified version of this conceptual approach for various F–F systems, and then in subsequent sections we describe how this approach

can be extended to account for through-space coupling between other kinds of magnetic nuclei, as exemplified in Figure 1. It should be acknowledged at the outset that various mathematically sophisticated and computationally oriented quantum mechanical theories of through-space F–F coupling have been presented in the past by other workers.⁴ However, although quantum mechanical approaches are intrinsically superior to our conceptual approach, they have not yet proved wholly successful in giving theoretical values of F–F coupling constants that are in consistently good agreement with the experimentally observed values. Therefore we continue to think it useful to offer our orbital overlap description as a basis on which to consider the phenomenon of through-space coupling.

2 FF SYSTEMS

Through-space F–F coupling can be attributed to the overlap of a pair of nominally lone-pair orbitals, one from each of the two coupled fluorine atoms.²² The situation for the particular intramolecular orientation found in the 1,8-difluoronaphthalene system (**1**), in which the C–F bonds are coplanar and approximately parallel to one another, is illustrated by the rough diagrams given in Figure 2. The relevant basis orbitals are the two in-plane one-center atomic lone-pair orbitals $p_{\text{F}\sigma}$ and $p'_{\text{F}\sigma}$ that would be characteristic of the fluorines if they were too far apart for these two orbitals to experience overlap interactions with each other. (For simplicity we neglect here the strong mixing of these $p_{\text{F}\sigma}$ and $p'_{\text{F}\sigma}$ orbitals with σ orbitals that are part of the carbon framework of the naphthalene system.) The F–F distance in (**1**), as measured by X-ray crystallography, is 0.2584 nm.²³ This is less than twice the 0.14 nm van der Waals radius of fluorine, so in fact the $p_{\text{F}\sigma}$ and $p'_{\text{F}\sigma}$ orbitals do overlap to a small extent. As shown schematically in Figure 2, this small F–F overlap transforms the pair of one-center atomic $p_{\text{F}\sigma}$ and $p'_{\text{F}\sigma}$ orbitals into a pair of two-center molecular orbitals, a weakly bonding orbital σ_{FF} and a weakly antibonding orbital σ^*_{FF} . Although

Figure 2 Schematic representations of the approximate shapes and relative energies of the bonding and antibonding molecular orbitals, σ_{FF} and σ^*_{FF} , that result from the overlap of the in-plane lone-pair orbitals, $p_{\text{F}\sigma}$ and $p'_{\text{F}\sigma}$, on two spatially proximate fluorine atoms oriented with their C–F bonds coplanar and essentially parallel, as in 1,8-difluoronaphthalene (**1**)

this combination of one filled bonding orbital and one filled antibonding orbital leads to no net chemical bonding between the two fluorine atoms, we believe it does provide a direct four-electron linkage that allows the transmittal of nuclear spin information between the two fluorine nuclei, and thereby gives rise to through-space F–F coupling.

In this lone-pair overlap theory through-space coupling is attributed to exactly the same kinds of interactions that are involved in through-bond coupling, namely Fermi contact interactions of the spins of the two magnetic nuclei with the spins of the surrounding electrons, electron correlation in accord with the Pauli principle for the two electrons within any given orbital, and Hund interactions between the spins of electrons in different orbitals. From this perspective the only distinction between through-space and through-bond coupling is a trivial one: through-space F–F coupling is transmitted by electrons that occupy weakly bonding and weakly antibonding orbitals, whereas through-bond coupling is transmitted by electrons that occupy strongly bonding orbitals. Given this picture, the term ‘through-space coupling’ can be seen as a misnomer. Perhaps this type of coupling would be more appropriately designated ‘proximate coupling’, ‘direct coupling’, or ‘nonbonded coupling’ but it seems unlikely that chemists will readily abandon the long-used term ‘through-space coupling’ and its juxtaposition with the term ‘through-bond coupling’.

In principle, there are five different valence-level fluorine basis orbitals whose overlap interactions should be considered with regard to through-space F–F coupling: the $2s$ lone-pair orbital s_F ; the in-plane $2p$ lone-pair orbital $p_{F\sigma}$; the out-of-plane $2p$ lone-pair orbital $p_{F\pi}$; the two-center bonding orbital σ_{CF} ; and the empty two-center antibonding orbital σ^*_{CF} . The $p_{F\sigma}-p'_{F\sigma}$ interaction illustrated in Figure 2 is only one of 14 different pairwise overlap interactions whose potential role in through-space F–F coupling should be taken into account. We have chosen to begin our presentation with the 1,8-difluoronaphthalene system because of its relative simplicity; each of the other 13 overlap interactions in this system can be considered to be either nonexistent or negligibly small in magnitude for various reasons. For example, the $s_F-p'_{F\pi}$, $p_{F\sigma}-p'_{F\pi}$, $p_{F\pi}-\sigma'_{CF}$, and $p_{F\pi}-\sigma^*_{CF}$ interactions are all zero by symmetry, as illustrated by the diagrams in Figure 3, and four other overlap interactions, $s_F-\sigma'_{CF}$, $s_F-\sigma^*_{CF}$, $p_{F\sigma}-\sigma'_{CF}$,

Figure 3 Schematic representations of F–F overlap interactions in the 1,8-difluoronaphthalene system (**1**) that are forbidden by symmetry

Figure 4 Schematic representation of overlap interactions in the 1,8-difluoronaphthalene system (**1**) that are nearly forbidden by symmetry

and $p_{F\sigma}-\sigma^*_{CF}$, are nearly zero in magnitude because of local symmetry considerations as illustrated in Figure 4.

Furthermore, all of the pairwise orbital interactions other than $p_{F\sigma}-p'_{F\sigma}$ suffer from the fact that their spatial overlaps at the F–F distance of about 0.258 nm are small relative to the spatial overlap involved in the dominant $p_{F\sigma}-p'_{F\sigma}$ interaction. Finally, many of the orbital interactions are unfavorable because of a large mismatch in the energies of the interacting pairs of basis orbitals. This information is summarized in Table 1.

The σ_{FF} and σ^*_{FF} molecular orbitals shown in Figure 2 both have nodes at or very near each fluorine nucleus, so the four electrons in these two orbitals do not have significant Fermi contact with the fluorine nuclei. Instead, the Fermi contact that is relevant for the observed F–F coupling involves the electrons in the $2s$ lone-pair orbitals, s_F and s'_F . (For simplicity, the Fermi contact interactions involving the electrons in the $1s$ orbital at each fluorine nucleus are ignored here.) For a fluorine atom whose nucleus has a spin-up alignment, for example, Fermi contact interactions give rise to an enhanced probability of finding the spin-down s_F electron in the region of the s_F orbital closer to the fluorine nucleus and a correspondingly enhanced probability of finding the spin-up

Table 1 Evaluation of the Relative Magnitudes of 14 Different Types of Pairwise Orbital Overlap Interactions between the Two Fluorine Atoms in 1,8-Difluoronaphthalene (**1**)

Orbital	Orbital'	Interaction Magnitude	Explanation Regarding Magnitude (see text)
s_F	s'_F	Negligible	Long distance
	$p'_{F\sigma}$	Negligible	Long distance, energy mismatch

s_F electron in the region of the s_F orbital more remote from the fluorine nucleus. This phenomenon, in which the spin-up and spin-down electrons in a given orbital have different spatial distributions of their electron densities, is known as spin polarization. The transmission pathway for the communication of nuclear spin information between the two fluorine nuclei is completed by way of Hund interactions between the electrons in the spin-polarized s_F and s'_F orbitals and the electrons in the σ_{FF} and σ_{FF}^* orbitals. As background for our explanation about how these particular Hund interactions control through-space F–F coupling we first consider three simpler systems: an isolated fluorine atom, the hydrogen fluoride molecule, and a C–F bond.

Theoretical calculations for an isolated fluorine atom have shown that Hund interactions between the electron in the half-occupied $2p$ orbital and the electrons in the spin-polarized $2s$ orbital lead to a preference for this $2p$ electron to have its spin aligned parallel to the net electron spin density in the inner region of the $2s$ orbital (and therefore antiparallel to the spin of the nucleus) as shown in Figure 5(a).²⁴

In the hydrogen fluoride molecule electron correlation effects cause one of the two electrons in the σ_{HF} bonding orbital to be closer to the fluorine nucleus and the other σ_{HF} electron to be closer to the hydrogen nucleus at a typical instant of time. This σ_{HF} orbital closely resembles a simple $2p_F$ orbital in the spatial distribution of its electron density, and as a consequence these two orbitals have analogous Hund interactions with their spin-polarized $2s_F$ orbitals. That is, the σ_{HF} electron that is closer to the fluorine nucleus prefers to have its spin aligned parallel to the electron spin density in the inner region of the spin-polarized fluorine $2s$ orbital. The net result is that a spin-up fluorine nucleus will cause the spin-down σ_{HF} electron to be located preferentially near the fluorine end of the hydrogen fluoride molecule as illustrated in Figure 5(b). As a consequence, the spin-up σ_{HF} electron will be located preferentially near the hydrogen end of the molecule. This spin-up σ_{HF} electron can experience direct Fermi contact interactions with the hydrogen nucleus, which means that there will be an energetic advantage if the hydrogen

nucleus has a spin-down alignment as shown in Figure 5(b). This simple picture predicts that the fluorine and hydrogen nuclei will prefer to have antiparallel nuclear spins, which accounts for the fact that the one-bond $J(FH)$ coupling constant for hydrogen fluoride molecule has been found to be positive in sign by both experimental and theoretical methods.²⁵

In contrast, the one-bond $J(FC)$ coupling constant for directly bonded carbon-13 and fluorine nuclei has been found to be negative in all known cases. Because of the usual electron correlation behavior the typical instantaneous configuration within the σ_{CF} orbital will have the two electrons located near opposite ends of the C–F bond. It has been argued earlier that the σ_{CF} electron that is located closer to the fluorine end of the bond experiences greater Hund interactions with the electron spin density in the outer region of the spin-polarized fluorine $2s$ orbital.²⁶ This reversal in the Hund behavior for the electrons in the C–F bond as compared with the H–F bond was attributed to the fact that the C–F bond is longer than the H–F bond.²⁶ The net result is a preference for the spin alignments shown in Figure 5(c), with the spin-up σ_{CF} electron located near the spin-up fluorine nucleus and therefore with the spin-down σ_{CF} electron located near the carbon nucleus. This spin-down σ_{CF} electron can experience direct Fermi contact interaction with the carbon-13 nucleus, which means that there will be an energy advantage if the carbon-13 nucleus has a spin-up alignment as shown in Figure 5(c). This simple picture predicts that the carbon-13 and fluorine nuclei will prefer to have parallel nuclear spins, consistent with the experimentally observed negative signs for carbon-fluorine one-bond coupling constants.

We turn now to the σ_{FF} and σ_{FF}^* orbitals (Figure 2) that are of interest for through-space F–F coupling. As illustrated in Figure 5(d) the orbital amplitudes are such that the two electrons in the bonding σ_{FF} orbital will be located preferentially in the region between the two nuclei, whereas the two electrons in the antibonding σ_{FF}^* orbital will be located preferentially in the two outer lobes of that orbital. As a consequence of electron correlation effects, one of the electrons in each orbital will be located preferentially near one of the fluorine nuclei while the other electron in each orbital will be located preferentially near the other fluorine nucleus. We hypothesize that because of the pronounced elongation of the bonding σ_{FF} orbital [the F–F distance of about 0.258 nm in a system such as (1) is considerably longer than the typical C–F bond distance of about 0.135 nm] the two σ_{FF} electrons experience Hund interactions preferentially with the outer regions of the spin-polarized s_F and s'_F orbitals, respectively, giving rise to a preference for the electron and nuclear spin alignments shown in Figure 5(d). This spin-polarization behavior is analogous to that noted for the C–F bond in Figure 5(c). We hypothesize further that the antibonding σ_{FF}^* orbital, which lacks the elongation of the σ_{FF} orbital because of the nodal plane at the midpoint of the line joining the two fluorine nuclei, shows spin-polarization behavior analogous to that of an isolated fluorine $2p$ orbital such that the two σ_{FF}^* electrons experience Hund interactions preferentially with the inner regions of the spin-polarized s_F and s'_F orbitals, respectively. This gives rise to a preference for the electron and nuclear spin alignments shown in Figure 5(d), which is analogous to the spin-polarization behavior noted for the F and HF systems in Figure 5(a) and (b). As a consequence of the cooperative effect

Figure 5 Schematic representations of the preferred electron and nuclear spin alignments for various systems: (a) the half-occupied $2p$ orbital of an isolated fluorine atom; (b) the σ_{HF} bonding orbital of the hydrogen fluoride molecule; (c) the σ_{CF} bonding orbital of a carbon–fluorine fragment; (d) the σ_{FF}^* antibonding and σ_{FF} bonding orbitals thought to be involved in through-space F–F coupling in a molecule such as (1)

of all four electrons in the σ_{FF} and σ_{FF}^* orbitals there is an energetic advantage if the two fluorine nuclei have antiparallel spins rather than parallel spins. In this way we can account for the fact that in all of the cases in which the signs of the F–F coupling constants have been determined experimentally for molecules in which the through-space mode of F–F coupling is thought to predominate, these signs have been found to be positive.⁶ Furthermore, the theory presented here leads to the conclusion that the magnitude of the through-space component of F–F coupling should depend on the extent to which the σ_{FF} and σ_{FF}^* orbitals are differentiated from one another in their electron densities in the region near the midpoint of the line connecting the two fluorine nuclei. This differentiation should depend in turn on the extent of overlap of the $p_{F\sigma}$ and $p'_{F\sigma}$ basis orbitals (see Figure 2), and this expectation leads to three experimentally testable predictions about the magnitude of $J(FF)^{TS}$: it should fall off exponentially with the distance between the two fluorine atoms, it should depend on orientation effects as well as distance effects, and it should not depend heavily on the π -electron withdrawing or π -electron supplying effects of any substituents that are located on the carbon framework that bears the two fluorine atoms. These implications are elaborated in the following paragraphs.

Many experimental studies have indicated that through-space F–F coupling has a very steep dependence on the distance between the coupled fluorine nuclei. One such study involves 15 compounds of types (16) and (17) (Figure 6) in which various peri substituents X and Y serve to perturb the F–F distance in predictable ways.^{9,27} Systems (16) and (17) have the disadvantage that the through-bond components of the experimentally measured total F–F coupling may be large enough to muddle the interpretation of the results. But these systems have two advantages: there is no complication from out-of-plane distortions of the fluorines of the kind found, for example, in systems related to (2) and (3); and the molecules are relatively straightforward to synthesize. The experimental results for (16) and (17) are given in Table 2.

The total coupling constants $J(FF)$ were measured by ^{19}F NMR spectroscopy and the distances between the two fluorine nuclei d_{FF} were determined by averaging the results obtained by MM2 and AM1 computations. The values of $J(FF)$ cover a wide range: from 28.1 Hz for 5,6-difluoroacenaphthene,

Figure 6 The types of 1,8-difluoronaphthalene (16) and 5,6-difluoroacenaphthene (17) derivatives for which $J(FF)$ values are listed in Table 2 and plotted in Figure 7

in which the two fluorine atoms are splayed apart as a consequence of the distortions in the peri-angles caused by the strained five-membered ring, to 82.3 Hz for 4,5-dicyano-1,8-difluoronaphthalene, in which the two fluorine atoms are pushed together as a consequence of the distortions of the peri-angles in the opposite sense caused by van der Waals repulsion between the two cyano groups. A semilogarithmic plot of $J(FF)$ against d_{FF} is shown in Figure 7. The data appear to be well correlated by the straight line shown in Figure 7, which leads to the relationship:

$$J(FF) = (9.64 \times 10^5) e^{-3.78 d_{FF}} \quad (2)$$

The average vertical deviation of points from the line in Figure 7 is ± 2.6 Hz and the correlation coefficient is 0.99. [We did not include in Figure 7 the data of 5,6-difluoroacenaphthylene, which would have given a point about 9.6 Hz above the correlation line. The reason for this large discrepancy remains obscure, although we suspect that the $-\text{CH}=\text{CH}-$ bridge might give rise to an enhanced through-bond component $J(FF)^{TB}$.]

Of course in order to use these data to provide a rigorous test of the validity of the lone-pair overlap theory one would need to plot not the total coupling constant $J(FF)$, but rather the through-space component $J(FF)^{TS}$, which is given by $J(FF) - J(FF)^{TB}$ where $J(FF)^{TB}$ is the through-bond component. Unfortunately, neither the magnitude nor the sign of $J(FF)^{TB}$ is known for any of the compounds in the series, although it seems likely from the large magnitudes of the observed coupling constants that the magnitude of $J(FF)^{TB}$ is small relative to $J(FF)$. Granted that the interpretation of

Table 2 Values of the Measured F–F Coupling Constants $J(FF)$ and the Calculated F–F Distances d_{FF} for Various Molecules of Types (16) and (17), and the Amounts by which these Experimental Coupling Constants Deviate from the Linear Correlation Plotted in Figure 7 and Expressed by Equation (2)

Figure 7 Semilogarithmic plot of $J(\text{FF})$ vs. d_{FF} for the derivatives of 1,8-difluoronaphthalene and 5,6-difluoroacenaphthene listed in Table 2 and pictured in Figure 6

the plot in Figure 7 is flawed by this uncertainty about the magnitude of the through-bond contribution to the observed $J(\text{FF})$ values, it nonetheless can be argued that the linear trend in this semilogarithmic plot provides at least qualitative support for the idea that through-space F–F coupling falls off exponentially with distance.

As an aside, an indication that there is a small through-bond component in the observed coupling constants in this series can be seen from the pattern exhibited by the small deviations of the experimental $J(\text{FF})$ values from the line plotted in Figure 7. The points for all seven of the compounds with π -acceptor substituents lie above the line: dicyano, +5.8; nitro, +5.6; anhydride, +3.9; diketone, +1.8; cyano, +1.4; quinoxaline, +0.3; and dioxime, +0.1 Hz. In contrast, the points for all six of the compounds with π -donor substituents lie below the line: methyl, –0.1; bromo, –0.9; chloro, –1.3; $-\text{CH}_2\text{CH}_2-$, –2.2; acetamido, –3.7; and amino, –7.8 Hz. The trend in these substituent effects is similar to the trend reported for the through-bond F–F coupling that takes place through the π -electron system in the 4-substituted-1,3-difluorobenzenes.²⁸ Relative to the F–F coupling constant of +6.6 Hz for 1,3-difluorobenzene itself, π -acceptor substituents at C-4 make $J(\text{FF})$ more positive and π -donor substituents at C-4 make $J(\text{FF})$ less positive by the following increments: nitro, +5.6; cyano, +4.3; chloro, –0.4; bromo, –0.5; methyl, –2.0; and amino, –8.7 Hz. It is perhaps not unreasonable to suspect that the 4-substituted-1,3-difluorobenzenes and the 4-substituted-1,8-difluoronaphthalenes may be analogous with respect to through-bond coupling through the π system because these two families of molecules share some common structural features; in each family the two fluorines are unconjugated with each other and separated by four bonds, and the substituent is *para* with respect to one of the fluorine atoms and also conjugated with the other fluorine atom.

Figure 8 Schematic representations of several types of orbital overlap that may play a role in through-space F–F coupling in 4,5-difluorophenanthrene systems such as (2)

For 4,5-difluorophenanthrenes such as (2), the C–F bonds are neither parallel nor coplanar, which makes the orbital overlap picture of through-space F–F coupling more complicated than that described above for the 1,8-difluoronaphthalenes such as (1). As illustrated in Figure 8, the orientation of the two fluorine atoms in the 4,5-difluorophenanthrene system may allow contributions to through-space F–F coupling from overlap interactions of the $p_{\text{F}\sigma}-\sigma'_{\text{CF}}$, $p_{\text{F}\sigma}-\sigma^{*'}_{\text{CF}}$, and $p_{\text{F}\sigma}-p'_{\text{F}\pi}$ types in addition to the major contribution arising from overlap interaction of the $p_{\text{F}\sigma}-p'_{\text{F}\sigma}$ type. These additional modes of overlap may be responsible for the fact that the measured value of 174 Hz for the F–F coupling constant for 4,5-difluoro-1-methylphenanthrene (2) is so much larger than the value of 97 Hz that would have been predicted from the correlation line in Figure 7 for the F–F distance of 0.2434 nm found experimentally for (2).²⁹ One should be cautious, however, about attempting quantitative comparisons involving $J(\text{FF})$ values in different systems such as 1,8-difluoronaphthalenes and 4,5-difluorophenanthrenes because of the uncertainties about the magnitudes and the signs of the through-bond components.

Yet another spatial array that leads to through-space F–F coupling is found in 1,12-difluorobenzo[*c*]phenanthrenes such as (3). For steric reasons this ring system adopts a helical structure such that the dominant orbital overlap interaction leading to through-space coupling between the two fluorine atoms involves the ‘out-of-plane’ $p_{\text{F}\pi}$ and $p'_{\text{F}\pi}$ lone-pair orbitals as illustrated in Figure 9. (For simplicity in this conceptual presentation we have neglected the strong mixing of these $p_{\text{F}\pi}$ and $p'_{\text{F}\pi}$ orbitals with various π orbitals that are characteristic of the benzo[*c*]phenanthrene ring system.) For the particular example of 4-bromo-1,12-difluorobenzo[*c*]phenanthrene the F–F distance is 0.2535 nm and the value of $J(\text{FF})$ is 45 Hz.^{8,29} At this F–F distance the correlation line for the 1,8-difluoronaphthalene system in Figure 7 would predict a significantly larger value of 66 Hz for $J(\text{FF})$. This discrepancy may reflect an orientation effect: the $p_{\text{F}\sigma}-p'_{\text{F}\sigma}$ overlap in the 1,8-difluoronaphthalene system is nearly optimum because the orbital axes are almost colinear, whereas the $p_{\text{F}\pi}-p'_{\text{F}\pi}$ overlap in the 1,12-difluorobenzo[*c*]phenanthrene system is less than optimum because of the significant departure of the orbital axes from colinearity, as shown in Figure 9. Once again, however, such comparisons between two different systems are risky because of our lack of knowledge of the through-bond contributions to the observed values of $J(\text{FF})$.

3 NF AND PF SYSTEMS

The lone-pair overlap theory presented here can be extended in a simple way to account for two other types of through-space coupling between spatially proximate atoms bearing lone

Figure 9 Schematic representations from two vantage points of the bonding and antibonding orbitals, σ_{FF} and σ_{FF}^* , resulting from the mutual overlap of the two 'out-of-plane' lone-pair orbitals, $p_{F\pi}$ and $p'_{F\pi}$, in 1,12-difluorobenzo[c]phenanthrene systems such as (3)

Figure 10 Schematic representations of the approximate shapes and relative energies of the bonding and antibonding molecular orbitals, σ_{NF} and σ_{NF}^* , that result from the overlap of an in-plane p_F lone-pair orbital and an sp^2_N lone-pair orbital on spatially proximate fluorine and nitrogen atoms oriented as in oxime acetate (12)

pairs, namely N–F and P–F coupling. The lone-pair orbital overlap interactions thought to be important for through-space N–F coupling are illustrated in Figure 10 for a structural array similar to that in oxime acetate (12). Through-space P–F coupling in molecules such as (14) can be accounted for in an analogous fashion. The dependence of N–F and P–F through-space coupling on distance and orientation effects appears to be similar to the dependence on these two factors found for the much more thoroughly studied through-space coupling in F–F systems.^{9,14,30}

4 HF, CF, AND CP SYSTEMS

The lone-pair overlap theory can be extended yet further by hypothesizing that through-space coupling can result from

lone-pair–bond-pair overlap as well as from lone-pair–lone-pair overlap as considered above. Through-space H–F and C–F coupling has been extensively documented in a variety of molecules in which either the hydrogen end or the carbon-13 end of a C–H bond is in close spatial contact with a fluorine 2p lone pair. As illustrated in Figure 11 and Figure 12, respectively, this coupling can be attributed to the overlap of the fluorine lone-pair orbital with the CH bonding orbital, augmented by some overlap of the fluorine lone pair with the corresponding CH antibonding orbital. The orbital mixing that arises from this overlap of these three basis orbitals creates three three-center molecular orbitals in each case, a pair of filled bonding and antibonding orbitals that are involved in the through-space coupling, and also one high-energy antibonding orbital that is empty and therefore plays no role in coupling.

In the F...HC orientation, for which the two filled three-center orbitals σ_{FHC} and σ_{FHC}^* are depicted in Figure 11, the amplitudes of the wave functions are such that the electron density in the bonding σ_{FHC} orbital is concentrated mostly in the middle region of the three-atom array, whereas the electron density in the antibonding σ_{FHC}^* orbital is concentrated mostly at the ends of the three-atom array. The spin-polarization pattern of these two pairs of electrons that appears to lead overall to the most favorable combination of Hund and Fermi interactions in the F...HC system is shown in Figure 13(a). By analogy with the F–F system discussed in the preceding section, we believe that the σ_{FHC} electron will experience Hund interactions at the fluorine atom primarily with the outer region of the spin-polarized s_F orbital, and therefore will prefer to have its spin aligned parallel to the spin of the fluorine nucleus. Also by analogy with the F–F system discussed above, we believe that the σ_{FHC}^* electron will experience Hund interactions at the fluorine atom primarily with the inner region of the spin-polarized s_F orbital, and therefore will prefer to have its spin aligned antiparallel to

Figure 11 Schematic representations of the approximate shapes and relative energies of the three-center bonding and antibonding molecular orbitals, σ_{FHC} and σ_{FHC}^* , that result from the overlap of a $p_{F\sigma}$ lone-pair orbital with a σ_{HC} orbital and a σ_{HC}^* orbital in a system such as (6) or (8) in which the fluorine atom is crowded against the hydrogen end of the CH fragment

Figure 12 Schematic representations of the shapes and relative energies of the three-center bonding and antibonding molecular orbitals, σ_{FCH} and σ_{FCH}^* , that result from the overlap of a $p_{F\sigma}$ lone-pair orbital with a σ_{CH} orbital and a σ_{CH}^* orbital in a system such as (9) in which the fluorine atom is spatially proximate to the carbon end of the CH fragment

Figure 13 Schematic representations of the preferred relative alignments of electron spins and nuclear spins in two systems: (a) the F...HC system depicted in Figure 11, and (b) the F...CH system depicted in Figure 12

the spin of the fluorine nucleus. The hydrogen and carbon-13 nuclei in this system interact with the σ_{FHC} and σ_{FHC}^* electrons by direct Fermi contact, which results in a preference for an antiparallel alignment of nuclear and electron spins in the regions around each of these nuclei. This analysis leads to the overall prediction that with respect to the through-space components of the H-F and C-F coupling in this system the hydrogen and fluorine nuclei in the F...HC system will prefer to have parallel nuclear spins, while the carbon and fluorine nuclei and also the carbon and hydrogen nuclei will prefer to have antiparallel nuclear spins, as shown in Figure 13(a). This prediction is in accord with the experimental demonstrations in these F...HC systems that the H-F coupling constants are negative and the C-F and C-H coupling constants are positive.^{10,11,31}

In the F...CH orientation, for which the two filled three-center orbitals σ_{FCH} and σ_{FCH}^* are depicted in Figure 12, the electron density in the bonding σ_{FCH} orbital is once again concentrated mostly in the middle region of the three-atom array while the electron density in the antibonding σ_{FCH}^* orbital is concentrated mostly at the ends of the three-atom array. The spin-polarization pattern of these two pairs of

Figure 14 Top views of (a) the lowest-energy π orbital and (b) one of the σ orbitals of the basal trisubstituted benzene ring in phosphorus compound (15)

electrons that appears to lead overall to the most favorable combination of Hund and Fermi interactions in the F...CH system is shown in Figure 13(b). This analysis leads to the overall prediction that with respect to the through-space components of H-F and C-F coupling in this system the hydrogen and fluorine nuclei and also the carbon and hydrogen nuclei will prefer to have antiparallel nuclear spins, consistent with the experimental observations that the H-F and C-H coupling constants in these F...CH systems are each positive in sign. The pattern in Figure 13(b) also predicts that $J(FC)^{TS}$ in this system should be negative. In fact, the total coupling constant $J(FC)$ is found to be small and negative in a particular F...CH system similar to (9),¹¹ but in contrast $J(FC)$ is found to be positive in system (9) itself and other F...CH systems.³¹ Perhaps this discrepancy arises because the through-bond component of the C-F coupling in molecules such as (9) is positive in sign and sufficiently large in magnitude to override the small negative through-space component of the C-F coupling that is predicted by the analysis shown in Figure 13(b). Alternatively, perhaps that analysis is simply not a reliable basis on which to predict the sign of $J(FC)$ in such systems.

The recently reported novel through-space coupling between phosphorus and carbon-13 nuclei in molecules such as (15) has been attributed to overlap interactions involving the lowest-energy π orbital of the basal trisubstituted benzene ring shown in Figure 14(a).^{16,17} This π orbital has the proper symmetry to mix with the lone-pair orbital on the phosphorus atom to generate two new filled seven-center molecular orbitals, one bonding and the other antibonding in the region between the phosphorus atom and the benzene ring. As an alternative possibility for consideration we suggest that the observed P-C coupling in (15) might involve mixing of the phosphorus lone-pair orbital with the σ orbital of the basal benzene ring shown in Figure 14(b). This mixing would generate a bonding and antibonding pair of filled 13-center molecular orbitals.

5 HH SYSTEMS

Having considered above how through-space coupling can be viewed as arising mainly from overlap interactions between two lone pairs or between one lone pair and one bond pair, it remains to consider the through-space coupling that arises from overlap interactions between two bond pairs. The large 18 Hz coupling between the two bridgehead hydrogen atoms in bicyclo[1.1.1]pentane (10) can be attributed to such interactions.^{12,13} As shown in Figure 15, the mutual overlap of the rear lobes of the two filled C-H bond orbitals σ_{CH} and

Figure 15 Schematic representations of the approximate shapes and relative energies of the four-center bonding and antibonding molecular orbitals, σ_{HCCH} and σ^*_{HCCH} , that result from the overlap of two filled CH bond-pair orbitals (with slight admixture of the corresponding two empty CH antibonding orbitals that are not shown explicitly here) oriented with their carbon ends spatially proximate as for the bridgehead C–H bonds in bicyclo[1.1.1]pentane (10)

Figure 16 Schematic representations of the preferred relative alignments of electron spins and nuclear spins in the HC ... CH system depicted in Figure 15

σ'_{CH} , modified slightly by overlap interactions of these filled orbitals with the empty antibonding orbitals σ^*_{CH} and σ^*_{CH} , would give rise to two new four-center molecular orbitals, one bonding and the other antibonding. This orbital mixing creates a four-center four-electron HCCH linkage for the transmittal of nuclear spin information among the four nuclei. As illustrated in Figure 16, this analysis correctly predicts a positive sign for $J(HH)$ in bicyclo[1.1.1]pentane (10).

One could imagine that through-space H–H coupling also might result when the hydrogen ends of two C–H bonds are brought into close proximity with one another. Many examples of through-space H–H couplings in this latter type of orientation have been reported, but they are very small in magnitude.

6 F–F COUPLING THROUGH NONBONDED INTERACTIONS WITH AN INTERVENING ORBITAL

Finally, the lone-pair overlap theory has proved itself to be useful by predicting the existence of a new type of through-space F–F coupling in which the two coupled fluorines are not crowded directly against one another but rather are each crowded in a nonbonding way against an intervening group X in molecules such as 1,8-difluoro-9-X-anthracenes.³² For example, various 1,8-difluoro-9-phenylanthracenes show values of $J(FF)$ in the range of 5–6 Hz as compared with

Figure 17 Schematic representations of the three mixed orbitals thought to be involved in through-space F–F coupling in the 1,8-difluoro-9-phenylanthracene system

$J(FF)$ values of less than 1 Hz for the corresponding 1,8-difluoroanthracenes.^{9,32} As a result of the steric demands in this system the phenyl group is oriented with its plane perpendicular to the plane of the anthracene ring. The pathway for the transmission of nuclear spin information in this system is believed to result from the overlap interactions of three basis orbitals, including two fluorine lone-pair orbitals and the lowest-energy filled π orbital on the intervening phenyl group. These interactions generate a set of three mixed orbitals, including one three-center bonding orbital σ_{FXF} , one three-center nonbonding orbital n_{FXF} , and one three-center antibonding orbital σ^*_{FXF} as in Figure 17. The lowest-energy π orbital is expected to have the most effective interactions here because ab initio molecular orbital calculations indicate that its energy is very close to that of the fluorine lone-pair orbitals.⁹ In addition, however, other π and π^* orbitals on the phenyl that possess the correct symmetry for overlap with the fluorine orbitals also may play a role in the F–X–F coupling.

1 INTRODUCTION

Nuclei which possess the property of spin also have an associated nuclear magnetic moment. It is the interaction between these nuclear magnetic moments and a strong applied magnetic field B_0 which forms the basis of the NMR experiment. This interaction, known as the Zeeman interaction, is always the most important spin interaction for spin- $\frac{1}{2}$ nuclei. In addition to the externally applied magnetic field, nuclei may also experience much smaller internal magnetic fields. For example, the field-induced motion of electrons generates small magnetic fields which modify the applied magnetic field and result in the phenomenon known as nuclear magnetic shielding or chemical shielding. In addition, neighboring nuclear spins may also create small magnetic fields which modify the applied magnetic field. There are two fundamental mechanisms by which one nuclear magnetic moment may interact with another: the *direct* magnetic dipole–dipole interaction and the *indirect* spin–spin interaction. The magnitude of the direct dipolar interaction is directly proportional to the inverse cube of the separation between two spins, while the indirect interaction does not depend on distance in any simple way since it is a two-stage process mediated by the intervening electrons. Because the mechanism of indirect spin–spin coupling involves electrons, this parameter depends on the detailed electronic structure of a molecule. Both the direct and indirect coupling interactions are bilinear in the nuclear spin operators (see below). In principle, the direct dipolar and indirect spin–spin interactions couple every spin of the sample with all others.

Most early NMR investigations were ^1H NMR studies, because of the relatively large magnetic moment of ^1H (hence its high inherent sensitivity to NMR detection), its large natural abundance (99.985%), and its ubiquitous presence in chemical compounds. The direct dipolar interaction has special significance in these studies since proton–proton direct dipolar interactions are largely responsible for the general appearance of ^1H NMR spectra of solid materials. Furthermore, the ^1H – ^1H dipolar interaction provided the first important application of NMR in chemistry. Specifically, Pake¹ used the ^1H – ^1H direct dipolar interaction to determine the H–H separation of water molecules in gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$): $r_{\text{H-H}} = 0.158 \text{ nm}$.

The indirect spin–spin coupling interaction was first observed as magnetic field-independent splittings in the NMR spectra of solution samples.^{2–4} In solution, the direct dipolar interaction averages to zero because of the rapid random tumbling motion of molecules. The first indirect spin–spin coupling constant J was reported by Proctor and Yu in 1951.² It involved the indirect spin–spin coupling between the antimony and fluorine nuclei of the SbF_6^- anion in an aqueous solution of NaSbF_6 ; $J(^{121}\text{Sb}, ^{19}\text{F}) = 1.9 \text{ kHz}$. Shortly after this report, Gutowsky and co-workers reported the observation of $J(^{31}\text{P}, ^{19}\text{F})$ in $\text{P}(\text{O})\text{Cl}_2\text{F}$ (1.2 kHz), $\text{P}(\text{O})\text{ClF}_2$ (1.1 kHz), and $\text{CH}_3(\text{O})\text{PF}_2$ (1.3 kHz).³ The first ^1H – ^1H electron-mediated spin–spin couplings were reported in the same year by Hahn and Maxwell.⁴ They studied the frequency modulation of ^1H NMR spin echoes arising from molecules with chemically nonequivalent hydrogen nuclei. For dichloroacetaldehyde (CHCl_2CHO), two distinct modulation frequencies were observed on the ^1H spin echo envelope: one corresponding to the difference in ^1H chemical shifts, and a second, much smaller frequency J which was independent of the applied magnetic field [$^3J(^1\text{H}, ^1\text{H}) = 0.7 \text{ Hz}$]. On the basis of their measurements, Hahn and Maxwell proposed that the Hamiltonian describing electron coupled spin interactions in isotropic fluids should be of the form $J_{N,N'} \mathbf{I}_N \cdot \mathbf{I}_{N'}$. However, for a pair of coupled spins residing in a molecule which is not rapidly tumbling in an isotropic fluid, Ramsey⁵ later pointed out that the energy of interaction $E_{N,N'}$ depends on the orientation of the spin pair in the applied magnetic field. In general, the energy of interaction is given by

$$E_{N,N'} = h \mathbf{I}_N \cdot \mathbf{J}_{N,N'} \cdot \mathbf{I}_{N'} + h J_{N,N'} \mathbf{I}_N \cdot \mathbf{I}_{N'} \quad (1)$$

where $\mathbf{J}_{N,N'}$ is a second rank tensor whose trace is zero and $J_{N,N'}$ is the isotropic indirect spin–spin coupling constant.

In solid samples, splittings arising from indirect spin–spin coupling were not observed until 1967.⁶ In the solid state, the magnitude of direct dipolar interactions among magnetically abundant spins, such as ^1H or ^{19}F , precluded the measurement of much smaller indirect spin–spin interactions. However, by spinning samples rapidly about an axis inclined at $54^\circ 44'$ with respect to the applied magnetic field, broadening due to anisotropic chemical shielding and direct dipolar interactions can be largely removed. Using this technique, known as magic angle spinning (MAS), Andrew et al.⁶ observed splittings due to $J(^{75}\text{As}, ^{19}\text{F})$ of 905 Hz, and $J(^{121}\text{Sb}, ^{19}\text{F})$ of 1820 Hz in the ^{19}F NMR spectra of solid KAsF_6 and KSbF_6 , respectively. From the ^{19}F NMR linewidths observed in nonspinning samples of these salts, the authors were able to conclude that the hexafluoroarsenate and hexafluoroantimonate anions are dynamically disordered. Rapid jumps of the MF_6 octahedra about their symmetry axes average *intramolecular* dipolar interactions to zero. Subsequently, VanderHart et al.⁷ studied the ^{19}F and ^{31}P NMR lineshapes of static samples of polycrystalline BaFPO_3 where the directly bonded ^{19}F and ^{31}P nuclei are coupled by both the direct dipolar and the indirect spin–spin coupling interactions. The authors indicated that with an accurate value of the ^{19}F – ^{31}P separation r_{FP} , one could calculate the contribution that the direct dipolar interaction makes to the overall ^{19}F or ^{31}P NMR lineshape and, in principle, determine the anisotropy in the indirect spin–spin coupling, a parameter which is usually inaccessible.

The objective of this article is to present an introductory discussion of how spin–spin coupling interactions are described

and how they manifest themselves in the NMR spectra of diamagnetic systems, particularly in NMR studies of solids. The discussion will focus on the indirect spin–spin coupling tensor $\mathbf{J}$, since detailed discussions of the direct dipolar interaction can be found in several textbooks on NMR.^{8–11} For pedagogical reasons, it is most convenient to focus the discussion on simple two-spin systems.

2 DIRECT DIPOLAR COUPLING

A nucleus with nonzero total spin angular momentum $\hbar\mathbf{I}$ also possesses a magnetic moment $\boldsymbol{\mu}$. The magnetic moment and angular momentum vectors are related by the magnetogyric ratio γ , a unique constant for any given isotope:

$$\boldsymbol{\mu} = \gamma\hbar\mathbf{I} \quad (2)$$

It is useful to consider the total static magnetic field emanating from a magnetic dipole. At a point P, the static field depends on the distance r and the angle θ between the magnetic dipole and P; the z component of the local field is $\gamma r^{-3}\hbar(3\cos^2\theta - 1)(\mu_0/4\pi)$. With $\theta = 0^\circ$, the local field 0.1 nm from a proton is 5.64 mT, several orders of magnitude less than the magnitude of typical external fields employed in NMR experiments.

From classical electrodynamics, the energy of interaction E between two magnetic dipoles, $\boldsymbol{\mu}_1$ and $\boldsymbol{\mu}_2$, separated by a distance r may be written as

$$E = [(\boldsymbol{\mu}_1 \cdot \boldsymbol{\mu}_2)r^{-3} - 3(\boldsymbol{\mu}_1 \cdot \mathbf{r})(\boldsymbol{\mu}_2 \cdot \mathbf{r})r^{-5}](\mu_0/4\pi) \quad (3)$$

where μ_0 is the permeability constant, $\mu_0 = 4\pi \times 10^{-7} \text{ kg m s}^{-2} \text{ A}^{-2}$. If the two dipoles $\boldsymbol{\mu}_1$ and $\boldsymbol{\mu}_2$ have the same orientation with respect to $\mathbf{r}$ then equation (3) becomes:

$$E = (\boldsymbol{\mu}_1 \cdot \boldsymbol{\mu}_2)r^{-3}(1 - 3\cos^2\theta)(\mu_0/4\pi) \quad (4)$$

where θ is the angle between the direction of the two magnetic dipoles and the vector $\mathbf{r}$ which separates them.

In NMR studies, one is generally concerned with nuclear magnetic moments. Consider two nuclei (1 and 2) separated by a distance r in a magnetic field (Figure 1). The quantum mechanical Hamiltonian describing the direct dipolar interaction, $\hat{\mathcal{H}}_{\text{DD}}$, is constructed by replacing the vectors $\boldsymbol{\mu}_1$ and $\boldsymbol{\mu}_2$ in equation (3) by their corresponding operators, $\gamma_1\hbar\hat{\mathbf{I}}_1$ and $\gamma_2\hbar\hat{\mathbf{I}}_2$:

$$\hat{\mathcal{H}}_{\text{DD}} = \gamma_1\gamma_2\hbar^2[(\hat{\mathbf{I}}_1 \cdot \hat{\mathbf{I}}_2)r^{-3} - 3(\hat{\mathbf{I}}_1 \cdot \mathbf{r})(\hat{\mathbf{I}}_2 \cdot \mathbf{r})r^{-5}](\mu_0/4\pi) \quad (5)$$

where γ_i is the magnetogyric ratio of nucleus i (in $\text{rad s}^{-1} \text{ T}^{-1}$), $\hat{\mathbf{I}}_i$ is the nuclear spin angular momentum operator, and $\mathbf{r}$ is the internuclear vector. In an NMR experiment, the direction of the magnetic moments is defined by the direction of the applied magnetic field $\mathbf{B}_0$.

If one expands the scalar products in equation (5),

$$\hat{\mathbf{I}}_1 \cdot \hat{\mathbf{I}}_2 = \hat{I}_{1x}\hat{I}_{2x} + \hat{I}_{1y}\hat{I}_{2y} + \hat{I}_{1z}\hat{I}_{2z} \quad (6)$$

$$\hat{\mathbf{I}}_1 \cdot \mathbf{r} = \hat{I}_{1x}x + \hat{I}_{1y}y + \hat{I}_{1z}z \quad (7)$$

Figure 1 Coordinate system used to describe the coupling of two spins $\hat{\mathbf{I}}_1$ and $\hat{\mathbf{I}}_2$ separated by a distance r . A strong applied magnetic field lies along the z axis

$$\hat{\mathbf{I}}_2 \cdot \mathbf{r} = \hat{I}_{2x}x + \hat{I}_{2y}y + \hat{I}_{2z}z \quad (8)$$

the direct dipolar Hamiltonian may be expanded and rewritten as

$$\begin{aligned} \hat{\mathcal{H}}_{\text{DD}} = & \gamma_1\gamma_2\hbar^2r^{-5}[\hat{I}_{1x}\hat{I}_{2x}(r^2 - 3x^2) + \hat{I}_{1y}\hat{I}_{2y}(r^2 - 3y^2) \\ & + \hat{I}_{1z}\hat{I}_{2z}(r^2 - 3z^2) - (\hat{I}_{1x}\hat{I}_{2y} + \hat{I}_{1y}\hat{I}_{2x})3xy \\ & - (\hat{I}_{1y}\hat{I}_{2z} + \hat{I}_{1z}\hat{I}_{2y})3yz - (\hat{I}_{1z}\hat{I}_{2x} + \hat{I}_{1x}\hat{I}_{2z})3zx] \\ & \times (\mu_0/4\pi) \end{aligned} \quad (9)$$

This equation can be expressed in matrix form:

$$\begin{aligned} \hat{\mathcal{H}}_{\text{DD}} = & hR \left\{ \begin{bmatrix} \hat{I}_{1x} & \hat{I}_{1y} & \hat{I}_{1z} \end{bmatrix} \right. \\ & \left. \begin{bmatrix} (r^2 - 3x^2)/r^2 & -3xy/r^2 & -3xz/r^2 \\ -3xy/r^2 & (r^2 - 3y^2)/r^2 & -3yz/r^2 \\ -3xz/r^2 & -3yz/r^2 & (r^2 - 3z^2)/r^2 \end{bmatrix} \begin{bmatrix} \hat{I}_{2x} \\ \hat{I}_{2y} \\ \hat{I}_{2z} \end{bmatrix} \right\} \end{aligned} \quad (10)$$

where R is defined as the direct dipolar coupling constant,

$$R = \gamma_1\gamma_2r^{-3}(\hbar/2\pi)(\mu_0/4\pi) \quad (11)$$

Equation (10) can be abbreviated as

$$\hat{\mathcal{H}}_{\text{DD}} = hR(\hat{\mathbf{I}}_1 \cdot \mathbf{D} \cdot \hat{\mathbf{I}}_2) \quad (12)$$

where $\mathbf{D}$ is the direct dipolar tensor.

It is easy to see that if the internuclear vector $\mathbf{r}$, lies along the z axis, then the dipolar tensor becomes diagonal:

$$\mathbf{D} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -2 \end{bmatrix} \quad (13)$$

This is the so-called principal axis system (PAS) of the dipolar tensor. Note that the principal components of the dipolar tensor

are axially symmetric, i.e. $D_{11} = D_{22}$. From equation (10) it is also obvious that the dipolar tensor is symmetric (i.e. $D_{\alpha\beta} = D_{\beta\alpha}$). Finally, it is also clear that the trace of the dipolar tensor is zero. This result indicates that the direct dipolar interaction does not influence the positions of peaks in liquid phase NMR spectra. It can also be shown that for isolated spin pairs in solid samples the time averaged expectation value of $\hat{\mathcal{H}}_{DD}$ is zero under conditions of MAS.¹² The sample must be spun rapidly with respect to the direct dipolar coupling constant R .

In order to discuss the NMR spectrum of two dipolar coupled spins in the solid state, it is convenient to transform equation (5) from Cartesian coordinates to spherical polar coordinates. This is readily accomplished by setting: $x = r \sin \theta \cos \phi$, $y = r \sin \theta \sin \phi$, $z = r \cos \theta$ and expressing $\hat{I}_x$ and $\hat{I}_y$ in terms of the raising and lowering operators $\hat{I}^+$ and $\hat{I}^-$, respectively:

$$\hat{I}^+ = \hat{I}_x + i\hat{I}_y, \quad \hat{I}^- = \hat{I}_x - i\hat{I}_y \quad (14)$$

Spin functions used to describe a nuclear spin state are eigenfunctions of the Zeeman Hamiltonian; they are often denoted by $|I, m\rangle$, where I is the nuclear spin quantum number and m is the z component of the spin angular momentum in units of $\hbar$ (i.e. $\hat{I}_z |I, m\rangle = m|I, m\rangle$). The spin quantum number m may take on values of $-I, -I+1, \dots, +I$. Thus, for spin- $\frac{1}{2}$ nuclei there are only two states $|\frac{1}{2}, \frac{1}{2}\rangle$ and $|\frac{1}{2}, -\frac{1}{2}\rangle$, which are generally denoted by $|\alpha\rangle$ and $|\beta\rangle$, respectively: $\hat{I}_z |\alpha\rangle = \frac{1}{2}|\alpha\rangle$ and $\hat{I}_z |\beta\rangle = -\frac{1}{2}|\beta\rangle$, while $\hat{I}^+ |\alpha\rangle = 0$, $\hat{I}^+ |\beta\rangle = |\alpha\rangle$, $\hat{I}^- |\alpha\rangle = |\beta\rangle$ and $\hat{I}^- |\beta\rangle = 0$. Further details concerning the quantum mechanics of angular momentum can be found elsewhere.^{8-11, 13, 14}

In spherical polar coordinates, the dipolar Hamiltonian can be expressed in terms of the so-called dipolar alphabet:

$$\hat{\mathcal{H}}_{DD} = hR(\hat{A} + \hat{B} + \hat{C} + \hat{D} + \hat{E} + \hat{F}) \quad (15)$$

Each of the terms $\hat{A}$ to $\hat{F}$ contains spin operators and a spatial term generally involving both θ and ϕ . Each term alters the spin functions used to describe a spin pair in a characteristic way. Explicit expressions for the terms $\hat{A}$ to $\hat{F}$ are given in several NMR textbooks.⁸⁻¹¹

To describe the NMR spectrum of a pair of equivalent homonuclear spins in a strong magnetic field, it is only necessary to consider the terms $\hat{A}$ and $\hat{F}$:

$$\hat{A} = -\hat{I}_{1z}\hat{I}_{2z}(3\cos^2\theta - 1) \quad (16)$$

$$\hat{B} = \frac{1}{4}[\hat{I}_1^+ \cdot \hat{I}_2^- + \hat{I}_1^- \cdot \hat{I}_2^+](3\cos^2\theta - 1) \quad (17)$$

Clearly, the $\hat{A}$ term does not alter the simple product spin functions $|\alpha\alpha\rangle$, $|\alpha\beta\rangle$, $|\beta\alpha\rangle$, and $|\beta\beta\rangle$ (e.g. $\hat{I}_{1z}\hat{I}_{2z}|\alpha\beta\rangle = (\frac{1}{2})(-\frac{1}{2})|\alpha\beta\rangle$). On the other hand, the $\hat{B}$ term contains the ‘flip-flop’ operator $\hat{I}_1^+\hat{I}_2^- + \hat{I}_1^-\hat{I}_2^+$, which alters the spin functions $|\alpha\beta\rangle$ to $|\beta\alpha\rangle$, and vice versa. For a pair of magnetically equivalent spins which are dipolar coupled in a strong applied magnetic field $\mathbf{B}_0$, the appropriate Hamiltonian operator is

$$\hat{\mathcal{H}} = \hat{\mathcal{H}}_Z + \hat{\mathcal{H}}_{DD} \quad (18)$$

where $\hat{\mathcal{H}}_Z = -\nu_0 h(\hat{I}_{1z} + \hat{I}_{2z})$, and $\nu_0 = \gamma B_0/2\pi$. To describe such a spin system, it is convenient to use the following basis functions:

$$|t_1\rangle = |\alpha\alpha\rangle \quad (19a)$$

$$|t_0\rangle = 2^{-1/2}(|\alpha\beta\rangle + |\beta\alpha\rangle)$$

$$|s\rangle = 2^{-1/2}(|\alpha\beta\rangle - |\beta\alpha\rangle) \quad (19b)$$

$$|t_{-1}\rangle = |\beta\beta\rangle \quad (19c)$$

Using these basis functions, the total matrix of the truncated dipolar Hamiltonian operator is diagonal. The resulting eigenvalues of $\hat{\mathcal{H}}$ (in frequency units) are:

$$|t_1\rangle : -\nu_0 - \frac{1}{4}R(3\cos^2\theta - 1) \quad (20a)$$

$$|t_0\rangle : \frac{1}{2}R(3\cos^2\theta - 1) \quad (20b)$$

$$|t_{-1}\rangle : \nu_0 - \frac{1}{4}R(3\cos^2\theta - 1) \quad (20c)$$

$$|s\rangle : 0 \quad (20d)$$

where θ is the angle between the dipolar vector and the applied magnetic field $\mathbf{B}_0$. Transitions involving the antisymmetric $|s\rangle$ level are symmetry-forbidden; therefore only two transitions, $\nu_0 \pm \frac{3}{4}R(3\cos^2\theta - 1)$, are allowed.

For any general orientation of a spin pair in an applied magnetic field, the two peaks are separated by $(\frac{3}{2})R(3\cos^2\theta - 1)$. Spectra from an isolated homonuclear spin pair in a hypothetical single crystal and powder sample are shown in Figure 2. The powder spectrum, known as a Pake powder pattern, is obtained by considering all orientations of the dipolar vector in $\mathbf{B}_0$ ($0^\circ \leq \theta \leq 180^\circ$; $0^\circ \leq \phi \leq 360^\circ$). The separation between the discontinuities, $(\frac{3}{2})R$, corresponds to $\theta = 90^\circ$ while the shoulders are separated by $3R$, which corresponds to the $\theta = 0^\circ$ orientation.

For a pair of unlike spins A and X, where the two spins have different magnetogyric ratios but both are spin $\frac{1}{2}$, it is only necessary to consider the A term of $\hat{\mathcal{H}}_{DD}$ since this is the only term in the dipolar alphabet which commutes with $\hat{\mathcal{H}}_Z$. The A-spin NMR spectrum consists of two peaks at $\nu_A \pm (\frac{1}{2})R(3\cos^2\theta - 1)$, where $\nu_A = \gamma_A B_0/2\pi$; the X-spin spectrum will be identical, except for the fact that it is centered about ν_X instead of ν_A . For unlike spins, the separation between the discontinuities in the A-spin or X-spin Pake powder pattern is R . If the X spin is a quadrupolar nucleus, calculation of the A-spin NMR spectrum may be more difficult, particularly if the high-field approximation is not applicable [i.e. $\hat{\mathcal{H}}_Z(X) \approx \hat{\mathcal{H}}_Q(X)$]. An instructive example of this problem was provided by Stoll et al.¹⁵ who discussed the ^{13}C NMR spectra of the $^{13}\text{C} - ^{14}\text{N}$ spin pair in a single crystal of $\text{K}_2\text{Pt}(\text{CN})_4\text{Br}_{0.3} \cdot 3\text{H}_2\text{O}$.

In practice, the chemical shielding interaction is orientation dependent, and thus it will also influence the detailed NMR lineshape. For protons, anisotropic chemical shielding generally causes a minor perturbation on the Pake doublet powder pattern, since it will be several orders of magnitude smaller than the direct dipolar interaction. However, for most other nuclei, the anisotropic chemical shielding (in frequency units) may be comparable to or greater than the dipolar interactions with adjacent nuclei. Under such conditions the

Figure 2 Calculated NMR spectra for two equivalent spins $\hat{I}_1$ and $\hat{I}_2$ which interact with one another by the direct dipolar interaction. From top to bottom: calculated spectra for three orientations of the internuclear vector in the applied magnetic field B_0 , $\theta = 0^\circ, 45^\circ, 90^\circ$, respectively. The bottom spectrum is the Pake powder pattern which results from a sum of spectra of individual crystallites which are randomly distributed in the sample. The calculated spectra have been convoluted with a Gaussian function to simulate weak dipolar interactions with more remote nuclei

‘A’-spin NMR spectrum of an AX-spin system in a static powder sample will consist of $2I + 1$ overlapping powder patterns, where I is the spin quantum number of X (Figure 3). One can often obtain valuable information concerning the orientation of chemical shielding tensors by analyzing dipolar chemical shift NMR spectra.^{14,16–18}

Typical values of the direct dipolar coupling constant involving directly bonded spin pairs range from a few hundred hertz to several kilohertz. For example, for the directly bonded ^{13}C – ^{15}N spin pair in the amide fragment of a peptide, $R \approx 1.3$ kHz; for the directly bonded ^{13}C – ^1H spin pair in a typical organic compound, $R \approx 23$ kHz. Further examples of direct dipolar coupling constants involving carbon are given in Table 1.

Much recent research is being focused on recoupling of dipolar interactions in high-resolution MAS experiments, e.g. the rotational resonance and rotational echo double resonance (REDOR) techniques.^{19–21} The objective of these experiments is to determine internuclear separations from small dipolar coupling constants. In fact, as will be outlined in Section 3.2, these experiments yield only an effective dipolar coupling constant

Figure 3 (a) A typical spin- $\frac{1}{2}$ NMR powder pattern of an isolated spin with anisotropic chemical shielding. The principal components of the chemical shielding tensor are easily identified from the powder pattern by the shoulders at σ_{11} and at σ_{33} and the discontinuity at σ_{22} . (b) Same as (a), but the influence of direct dipolar coupling with an adjacent spin- $\frac{1}{2}$ nucleus is illustrated. The direct dipolar interaction causes an apparent splitting of the chemical shielding powder pattern

Table 1 Typical Direct and Indirect Spin–Spin Coupling Constants Involving Carbon

X	Compound	R^a (Hz)	$J(M,^{13}\text{C})_{\text{iso}}$ (Hz)	$K(M,\text{C})_{\text{iso}}^b$
^{13}C	$\text{C}(\text{CH}_3)_4^c$	2080	37	4.9
^{29}Si	$\text{Si}(\text{CH}_3)_4^c$	–920	–50	8.4

which is dependent on the anisotropy in the indirect coupling as well as the direct dipolar coupling constant R .

As an aside, it is important to indicate that anisotropic molecular vibrations can result in a subtle vibrationally induced asymmetry of the dipolar coupling tensor; this will be most important when the direct dipolar coupling involves a hydrogen nucleus.^{22,23}

The discussion presented here can be extended to more complex spin systems. For example, Van Hecke et al.²⁴ studied the ^1H and ^{19}F NMR spectra of the bifluoride ion in a single crystal of KHF_2 . In addition, systems containing the $^{13}\text{CH}_2$ fragment have attracted considerable attention.^{25–27}

3 INDIRECT SPIN–SPIN COUPLING

As mentioned in Section 1, indirect spin–spin coupling is a two-stage process. One can imagine the spin at one nucleus perturbing the electrons in its vicinity. The resulting

perturbation is transferred via the electronic framework of the molecule to electrons in the vicinity of the second nucleus. The distinctive ways in which a nuclear moment perturbs the surrounding electrons is known as a mechanism for indirect spin–spin coupling (see below). The total indirect spin–spin coupling constant J is a sum of the contributions arising from each mechanism. Clearly, the contribution that each coupling mechanism makes to J is directly proportional to the product of the nuclear magnetic moments of the two coupled nuclei. The sign of indirect spin–spin coupling constants can be either positive or negative. If the indirect spin–spin coupling interaction stabilizes the antiparallel arrangement of the nuclear spins, then the indirect spin–spin coupling is positive. The magnitudes of isotropic indirect spin–spin coupling constants are readily measured in solution NMR studies. Values as small as 0.10 Hz are routinely measured. Isotropic values rarely exceed 30 kHz; however, a ^{199}Hg , ^{199}Hg indirect spin–spin coupling constant of 139.6 kHz has been reported for the Hg_3^{2+} ion.²⁸ Typical values of one-bond indirect spin–spin coupling constants involving carbon, $^1J(\text{M}, ^{13}\text{C})_{\text{iso}}$, are given in Table 1. The literature on isotropic indirect spin–spin coupling constants is extensive.²⁹ Over the past 45 years many important relationships between spin–spin coupling constants J_{iso} and molecular structure have been established. On the other hand $\mathbf{J}$ tensors are difficult to characterize experimentally. Furthermore, reliable quantum mechanical calculations of $\mathbf{J}$ tensors or their corresponding isotropic values are a challenge.³⁰ Here, the properties of the $\mathbf{J}$ tensor are outlined. This is followed by a discussion of how the $\mathbf{J}$ tensor can be experimentally characterized from solid state NMR measurements.

3.1 Nature of $\mathbf{J}$ Coupling Tensors

The Hamiltonian describing the indirect spin–spin coupling of two spins, $\mathbf{I}_1$ and $\mathbf{I}_2$, may be expressed as

$$\hat{\mathcal{H}}_J = h \hat{\mathbf{I}}_1 \cdot \mathbf{J} \cdot \hat{\mathbf{I}}_2 \quad (21)$$

where $\mathbf{J}$ is the indirect spin–spin coupling tensor. The $\mathbf{J}$ tensor is a second rank tensor which is described by nine matrix elements in a Cartesian coordinate system. For example, in a particular molecular fixed axis system, the $\mathbf{J}$ tensor might be represented by the matrix:

$$\mathbf{J} = \begin{bmatrix} J_{aa} & J_{ab} & J_{ac} \\ J_{ba} & J_{bb} & J_{bc} \\ J_{ca} & J_{cb} & J_{cc} \end{bmatrix} \quad (22)$$

In contrast to the direct dipolar tensor, the $\mathbf{J}$ tensor has a nonvanishing trace.

A general second-rank tensor can be decomposed into a sum of irreducible tensors of rank $l = 0, 1, 2$.^{31,32} Thus the indirect spin–spin coupling tensor can be written as

$$\mathbf{J} = \mathbf{J}^{(0)} + \mathbf{J}^{(1)} + \mathbf{J}^{(2)} \quad (23)$$

In equation (23) the $l = 0$ tensor is the isotropic part of the tensor,

$$\mathbf{J}^{(0)} = \left(\frac{1}{3} \text{Tr } \mathbf{J}\right) \mathbf{1} = J_{\text{iso}} \mathbf{1} \quad (24)$$

where $\text{Tr } \mathbf{J} = (J_{aa} + J_{bb} + J_{cc})$ and $\mathbf{1}$ is the unit tensor with diagonal components equal to 1 and all off-diagonal elements zero. The second term in equation (23), $l = 1$, is the antisymmetric part of the tensor,

$$\mathbf{J}^{(1)} = \frac{1}{2}(\mathbf{J} - \mathbf{J}^t) \quad (25)$$

where $\mathbf{J}^t$ is the transpose of $\mathbf{J}$. The transpose of a 3×3 matrix is obtained by replacing the first column by the first row, the second column by the second row, and the third column by the third row. Since the diagonal elements of $\mathbf{J}$ and $\mathbf{J}^t$ are identical, the diagonal elements of the antisymmetric tensor are zero. The third term in equation (23), $l = 2$, is the symmetric part of the tensor, defined as

$$\mathbf{J}^{(2)} = \frac{1}{2}(\mathbf{J} + \mathbf{J}^t) - J_{\text{iso}} \mathbf{1} \quad (26)$$

Although the trace of the symmetric part is zero, the diagonal elements are, in general, not zero.

To a very good approximation, only tensors with $l = 0$ and $l = 2$ affect the general appearance of an NMR spectrum.³² That is, even though the antisymmetric components of a particular $\mathbf{J}$ tensor may be non zero, these components do not perturb the observed spectrum in first order. In fact, the existence of antisymmetric components in any indirect spin–spin coupling tensor has never been demonstrated experimentally.³³

For each symmetric $\mathbf{J}$ tensor ($\mathbf{J}^{(0)} + \mathbf{J}^{(2)}$), there exists a principal axis system for which the matrix $\mathbf{J}^{(2)}$ is diagonal. The diagonal elements, denoted by J_{xx} , J_{yy} , and J_{zz} , are called the principal elements, with the convention:

$$|J_{zz}| \geq |J_{xx}| \geq |J_{yy}| \quad (27)$$

The principal axis system of the $\mathbf{J}$ tensor is often fixed by the molecular symmetry. For a linear molecule there are only two components, $J_{\parallel}$ and $J_{\perp}$, describing the coupling of the nuclear spin components parallel and perpendicular to the internuclear axis, respectively. Similarly, there are only two non-zero components of the symmetric $\mathbf{J}$ tensor for a pair of nuclei sitting on the highest order symmetry axis of molecules in the point groups D_{nd} , D_{nh} , C_{nh} , C_{nv} , and S_n , with $n \geq 3$. The number of independent components in the $\mathbf{J}$ tensor for other group symmetries has been tabulated by Buckingham et al.³³ and by Robert and Wiesenfeld.³⁴

In describing the orientation dependence of NMR parameters, it is often useful to define the anisotropy of the parameter. This provides a measure of the maximum orientation dependence of that particular parameter. The anisotropy of the indirect spin–spin coupling tensor is usually defined as

$$\Delta J = J_{zz} - \frac{1}{2}(J_{xx} + J_{yy}) \equiv \frac{3}{2}(J_{zz} - J_{\text{iso}}) \quad (28)$$

In the case of axial symmetry, equation (28) simplifies to

$$\Delta J = J_{\parallel} - J_{\perp} \quad (29)$$

In such cases it is straightforward to show that

$$\mathbf{J} = \begin{bmatrix} J_{\perp} & 0 & 0 \\ 0 & J_{\perp} & 0 \\ 0 & 0 & J_{\parallel} \end{bmatrix} = J_{\text{iso}} \mathbf{1} + \begin{bmatrix} -\Delta J/3 & 0 & 0 \\ 0 & -\Delta J/3 & 0 \\ 0 & 0 & 2\Delta J/3 \end{bmatrix} \quad (30)$$

Under these conditions the Hamiltonian equation (21), becomes

$$\hat{\mathcal{H}}_{\mathbf{J}} = hJ_{\text{iso}}\hat{\mathbf{I}}_1 \cdot \hat{\mathbf{I}}_2 + h\hat{\mathbf{I}}_1 \cdot \mathbf{J}' \cdot \hat{\mathbf{I}}_2 \quad (31)$$

where $\mathbf{J}'$ is the traceless ‘ $\Delta\mathbf{J}$ ’ tensor which is of the same form as the dipolar tensor [equation (13)]. Since the trace of $\mathbf{J}'$ is zero, it is clear that the anisotropy in the principal components of $\mathbf{J}$ has no influence on the NMR spectra of isotropic fluids. In principle, ΔJ could provide a mechanism for spin–lattice relaxation, but this mechanism has never been identified as being important.³⁵

Ramsey’s theory⁵ serves as the basis for most theoretical discussions of indirect spin–spin coupling tensors. Following Ramsey, the nonrelativistic Hamiltonian describing nuclear spin, electron spin interactions can be represented by

$$\hat{\mathcal{H}} = \hat{\mathcal{H}}^{(1a)} + \hat{\mathcal{H}}^{(1b)} + \hat{\mathcal{H}}^{(2)} + \hat{\mathcal{H}}^{(3)} \quad (32)$$

The first two terms are the so-called orbital diamagnetic (OD) and orbital paramagnetic (OP) terms which account for the interaction between the nuclear magnetic moments and the orbital motion of the electrons. The third term, $\hat{\mathcal{H}}^{(2)}$, accounts for the spin-dipolar (SD) interactions between the nuclear and electronic magnetic moments. The last term, $\hat{\mathcal{H}}^{(3)}$, accounts for the interaction of the nucleus and the electron spin at the nucleus; this interaction is known as the Fermi contact (FC) interaction. Using these interactions, various approaches, generally based on second-order perturbation theory, are used to calculate indirect nuclear spin–spin coupling tensors. Five separate terms contribute to the overall $\mathbf{J}$ tensor:

$$\mathbf{J} = \mathbf{J}^{(1a)} + \mathbf{J}^{(1b)} + \mathbf{J}^{(2)} + \mathbf{J}^{(3)} + \mathbf{J}^{(4)} \quad (33)$$

The orbital diamagnetic contribution $\mathbf{J}^{(1a)}$ involves only the ground electronic state of the system. The other four terms involve the following combination of interactions: OP–OP, SD–SD, FC–FC, and FC–SD. The OP term has matrix elements between the ground state and excited singlet states while the SD and FC interactions have matrix elements between the ground state and excited triplet states. The FC–FC contribution to the $\mathbf{J}$ tensor is completely isotropic. In contrast, the FC–SD cross term does not contribute to the isotropic value of the spin–spin coupling tensor, but only to its anisotropy, thus the trace of the tensor arising from this term is zero. The other two terms contribute to both the isotropic and anisotropic portion of the total $\mathbf{J}$ tensor.

Explicit expressions for each of the five terms in equation (33) are given in several standard NMR texts and review articles.^{29,36} It should be mentioned that the theory of Ramsey is a nonrelativistic theory which assumes that orbital and spin angular momenta are L – S coupled. Pyykkö³⁷ has developed a relativistic analogue of Ramsey’s theory based on j – j coupling. Undoubtedly, relativistic effects will be important for indirect spin–spin coupling constants involving nuclei beyond the second row. Furthermore, it has been found that consideration of relativistic effects in extended Hückel calculations tends to increase the calculated anisotropy of spin–spin coupling tensors.³⁸

In equation (33), each term is of the form $\gamma_N\gamma_{N'}/h\mathbf{K}_{N,N'}/4\pi^2$, where $\mathbf{K}_{N,N'}$ is called the reduced indirect

spin–spin coupling tensor involving nuclei N and N' . The reduced coupling tensor is independent of the magnitude of the nuclear magnetic moments and, therefore, it is useful in comparing indirect spin–spin coupling tensors involving different spin pairs. Note that $\mathbf{J}_{N,N'}$ has units of Hz (s^{-1}) and $\mathbf{K}_{N,N'}$ has units of $\text{N A}^{-2} \text{m}^{-3}$ (or, equivalently, $\text{T}^2 \text{J}^{-1}$).³⁹ The isotropic indirect spin–spin coupling constants involving carbon in Table 1 have also been expressed as reduced coupling constants. As one descends the group 14 elements, M, of the Periodic Table in the series $\text{M}(\text{CH}_3)_4$, $\mathbf{K}(\text{M},\text{C})$ increases with atomic number Z_M . Similarly, in the series X_3MPR_3 , where M is a group 13 element, $\mathbf{K}(\text{M},\text{P})$ increases as follows: $\approx 10 \times 10^{20} \text{N A}^{-2} \text{m}^{-3}$ ($\text{M} = \text{B}$), $\approx 20 \times 10^{20} (\text{Al})$, $\approx 65 \times 10^{20} (\text{M} = \text{Ga})$, and $\approx 100 \times 10^{20} (\text{M} = \text{In})$.⁴⁰ Qualitatively, these trends can be rationalized by considering only the Fermi contact mechanism; however, there is evidence that the tensor, $\mathbf{K}(\text{In},\text{P})$, in $\text{Br}_3\text{InP}[\text{4}-(\text{CH}_3\text{O})-\text{C}_6\text{H}_4]_3$ is anisotropic, implying that mechanisms other than the Fermi contact contribute to this particular $\mathbf{J}$ tensor.⁴⁰

3.2 Measurement of $\mathbf{J}$ Coupling Tensors

Using NMR spectroscopy, $\mathbf{J}$ tensors can be characterized by studying the spectra of single crystals,^{41–43} solid powder samples,^{44–47} or samples oriented in liquid crystalline solvents.^{48,49} In isotropic fluids, only the isotropic indirect spin–spin coupling constant (a scalar) is measured. For simple molecules in the gas phase ΔJ can, in principle, be measured using molecular beam magnetic resonance techniques.⁵⁰ So far, the latter technique has only been successfully applied to thallium fluoride.⁵¹ In this case, $J(^{205}\text{Tl}, ^{19}\text{F})_{\text{iso}} = -13.3 \pm 0.7 \text{ kHz}$ and $\Delta J(^{205}\text{Tl}, ^{19}\text{F}) = 11.1 \pm 0.7 \text{ kHz}$. Below, the NMR spectra of a simple heteronuclear two-spin system residing in a rigid solid will be discussed. Particular emphasis is placed on describing how the NMR spectra depend on ΔJ .

Consider a pair of heteronuclear spins A and X, also denoted by ‘1’ and ‘2’, respectively, which are coupled to one another via direct and indirect spin–spin interactions in a strong applied magnetic field. Furthermore, if the $\mathbf{J}$ tensor is axially symmetric and coincident with the direct dipolar tensor, $J_{\parallel}$ and $J_{\perp}$ correspond to orientations where the internuclear vector is parallel and perpendicular, respectively, to the applied magnetic field. Under these conditions the appropriate nuclear spin Hamiltonian for the A spin is:

$$\hat{\mathcal{H}} = \hat{\mathcal{H}}_Z + \hat{\mathcal{H}}_{\text{CS}} + \hat{\mathcal{H}}_{\text{DD}} + \hat{\mathcal{H}}_J \quad (34)$$

where $\hat{\mathcal{H}}_{\text{CS}}$ accounts for the anisotropic chemical shielding. For now it is assumed that the chemical shielding is independent of the orientation of the molecule in the applied magnetic field. Both $\hat{\mathcal{H}}_{\text{DD}}$ and $\hat{\mathcal{H}}_J$ are of the same form. As already indicated

$$\hat{\mathcal{H}}_{\text{DD}} = hR\hat{\mathbf{I}}_1 \cdot \mathbf{D} \cdot \hat{\mathbf{I}}_2 = -hR\hat{I}_{1z}\hat{I}_{2z}(3\cos^2\theta - 1) \quad (35)$$

Similarly, equation (31) becomes

$$\begin{aligned} \hat{\mathcal{H}}_J &= h\hat{\mathbf{I}}_1 \cdot \mathbf{J} \cdot \hat{\mathbf{I}}_2 = hJ_{\text{iso}}\hat{I}_{1z}\hat{I}_{2z} + h(\Delta J/3)\hat{I}_{1z}\hat{I}_{2z} \\ &\quad \times (3\cos^2\theta - 1) \end{aligned} \quad (36)$$

Using the basic product functions for an AX spin system consisting of two spin- $\frac{1}{2}$ nuclei, it is straightforward to calculate the four energy levels. The A spectrum results from two allowed transitions at:

$$\nu = \nu_A - m_X J_{\text{iso}} + m_X [R - (\Delta J/3)](3 \cos^2 \theta - 1) \quad (37)$$

where $m_X = +\frac{1}{2}$ or $-\frac{1}{2}$. The two A peaks are separated by

$$\Delta \nu = J_{\text{iso}} - [R - (\Delta J/3)](3 \cos^2 \theta - 1) \quad (38)$$

Often, the term $R - (\Delta J/3)$ in equations (37) and (38) is called the effective dipolar coupling constant R_{eff} ; thus,

$$\Delta \nu = J_{\text{iso}} - R_{\text{eff}}(3 \cos^2 \theta - 1) \quad (39)$$

The splittings, $\Delta \nu$, that would be observed as the A-X bond axis, r_{AX} , in a single crystal is rotated about an axis perpendicular to $\mathbf{B}_0$ are shown in Figure 4. Several important points emerge from equations (37)–(39) and Figure 4:

1. For a single crystal sample, equation (39) also applies if the chemical shielding is anisotropic.
2. From Figure 4 it is apparent that the maximum variation in the splitting of the A peaks is $3R_{\text{eff}}$. Experimentally, one cannot separately determine R and ΔJ ; only R_{eff} can be measured. If a value for the internuclear separation r_{AX} can be determined independently by diffraction techniques, R can be calculated from equation (11), and ΔJ can be obtained from the experimental value of R_{eff} .
3. The relative sign of J_{iso} and R_{eff} can be deduced from single crystal measurements. If J_{iso} and R_{eff} have the same sign, the maximum splitting will be $|J_{\text{iso}}| + |R_{\text{eff}}|$, while the minimum splitting will be $|J_{\text{iso}}| - 2|R_{\text{eff}}|$. On the other hand, if J_{iso} and R_{eff} have opposite signs, the maximum splitting will be $|J_{\text{iso}}| + 2|R_{\text{eff}}|$ and the minimum splitting will be $|J_{\text{iso}}| - |R_{\text{eff}}|$.

Figure 4 Separation between the two allowed A spin transitions for an AX spin system in a single crystal as a function of the orientation in the applied magnetic field $\mathbf{B}_0$. Splittings are given in units of R_{eff} . The rotation axis is perpendicular to $\mathbf{B}_0$ and the rotation angle θ is defined as the angle between r_{AX} and $\mathbf{B}_0$

Figure 5 The effect of ΔJ on the A-spin NMR spectrum of a powder sample containing a heteronuclear AX spin pair. In each case $J_{\text{iso}} = 5R$. With $\Delta J = 3R$, each subspectrum collapses into an isotropic peak

In the case of a powder sample, the A spectrum consists of two subspectra corresponding to $m_X = +\frac{1}{2}$ and $m_X = -\frac{1}{2}$. Each subspectrum is one-half of a conventional Pake powder pattern (Figure 5). The isotropic frequencies of the two subspectra are separated by J_{iso} . (Note that if $J_{\text{iso}} = 0$, conventional Pake powder patterns would be observed except for the case where $\Delta J = 3R$.)

In calculating the spectra shown in Figure 5, the chemical shielding is assumed to be isotropic (i.e. independent of orientation). In order to calculate the A-spin NMR powder lineshape, allowing for the possibility of anisotropic chemical shielding, it is convenient to define the orientation of the internuclear vector in the PAS of the chemical shielding tensor (Figure 6). In this case one can show that the frequency of the A-spin transitions are given by:

$$\nu_m(\theta, \phi) = \nu_L - \nu_{\text{CS}} - m_X \nu_D - m_X J_{\text{iso}} \quad (40)$$

$$\nu_L = \gamma_A B_0 / 2\pi \quad (41)$$

$$\nu_{\text{CS}} = \left(\frac{\gamma_A B_0}{2\pi} \right) (\sigma_{11} \sin^2 \theta \cos^2 \phi + \sigma_{22} \sin^2 \theta \sin^2 \phi + \sigma_{33} \cos^2 \theta) \quad (42)$$

$$\nu_D = R_{\text{eff}} \{ 1 - 3[\sin \beta \sin \theta \cos(\phi - \alpha) + \cos \beta \cos \theta]^2 \} \quad (43)$$

Figure 6 The orientation of an internuclear vector r_{AX} in the principal axis system (PAS) of the A-spin shielding tensor. The angles θ and ϕ define the orientation of B_0 in the PAS of the shielding tensor

where the principal components of the chemical shielding tensor σ_{11} , σ_{22} , and σ_{33} are defined such that $\sigma_{11} \leq \sigma_{22} \leq \sigma_{33}$. All angles are defined in Figure 6. In deriving equations (40)–(43), it is assumed that the $\mathbf{J}$ tensor is axially symmetric and that the $\mathbf{J}$ and $\mathbf{D}$ tensors are coincident. Even with these assumptions, the A-spin NMR powder spectrum may prove difficult to analyze.¹⁸

From the above discussion, it should be clear that if one is interested in characterizing a particular $\mathbf{J}$ tensor using solid state NMR techniques, single crystal NMR studies are desirable. Unfortunately, few studies have been reported to date.^{41–43} Such studies are generally tedious, require relatively large single crystals (e.g. sides of 1 mm or greater), and the results of an X-ray or neutron diffraction investigation. In some cases, values of ΔJ can be obtained from the analysis of NMR powder spectra which arise from isolated spin pairs.^{44–47} For example, for a series of mercury phosphine complexes values of $\Delta J(^{199}\text{Hg}, ^{31}\text{P})$ of the order of 5 kHz have been estimated from the analysis of static ^{31}P NMR spectra.^{46,47} Below, the general procedure used to analyze such spectra is outlined.

The ^{31}P CP MAS spectrum of one of these complexes, $[\text{HgP}(o\text{-tolyl})_3(\text{NO}_3)_2]_2$, is shown in Figure 7. The natural abundance of ^{199}Hg is 16.84% ($I = \frac{1}{2}$), therefore the ^{31}P NMR spectrum of the molecules containing the ^{199}Hg – ^{31}P spin pair is a doublet with separation $J(^{199}\text{Hg}, ^{31}\text{P})_{\text{iso}} = 9660$ Hz. The sign of this indirect spin–spin coupling constant is assumed to be positive on the basis of double resonance NMR experiments carried out on related molecules in solution. The only other naturally occurring isotope of mercury with nonzero spin is ^{201}Hg ($I = \frac{3}{2}$; natural abundance 13.22%), but the ^{31}P NMR spectrum of the ^{201}Hg – ^{31}P spin pair is very broad and difficult to observe at room temperature. Molecules containing other naturally occurring isotopes of mercury give rise to a single isotropic peak, since the mercury nuclei of these isotopes have $I = 0$. In order to obtain R_{eff} , it is most advantageous to obtain a ^{31}P NMR spectrum of a static powder sample (Figure 8). Again, the intense central feature in the ^{31}P NMR spectrum corresponds to molecules where mercury nuclei have a spin $I = 0$.

Analysis of this central lineshape provides the principal components of the phosphorus shielding tensor, information required to analyze the subspectra arising from the ^{199}Hg – ^{31}P spin pairs. In this case, the phosphorus shielding tensor is

Figure 7 The ^{31}P NMR spectrum of a powder sample of $[\text{HgP}(o\text{-tolyl})_3(\text{NO}_3)_2]_2$ obtained with relatively slow magic angle sample spinning ($\nu_r = 892$ Hz). The spectrum was obtained with high-power ^1H decoupling and cross polarization in an applied magnetic field of 4.7 T, corresponding to a ^{31}P NMR Larmor frequency of 81.0 MHz. Frequencies are given with respect to the isotropic ^{31}P NMR peak of solid $\text{NH}_4\text{H}_2\text{PO}_4$. The horizontal arrow indicates the separation between the isotropic peak positions of the ^{199}Hg satellite peaks ($J_{\text{iso}} = 9660$ Hz). Note that the spinning sidebands of the high-frequency satellite peak, $m_{\text{Hg}-199} = -\frac{1}{2}$, extend over a much larger range than do those of the low-frequency satellite corresponding to $m_{\text{Hg}-199} = \frac{1}{2}$

Figure 8 The ^{31}P NMR spectrum of a static powder sample of $[\text{HgP}(o\text{-tolyl})_3(\text{NO}_3)_2]_2$ obtained at 81.0 MHz

approximately axially symmetric with the unique component along the Hg–P bond axis. Inspection of the spectrum shown in Figure 8 indicates that the high-frequency subspectrum corresponding to $m_{\text{Hg}-199} = -\frac{1}{2}$ is stretched (breadth ≈ 4.75 kHz), while the low-frequency subspectrum corresponding to $m_{\text{Hg}-199} = \frac{1}{2}$ is squeezed (breadth ≈ 1.45 kHz) relative to the intense central powder pattern $[(\nu_{\parallel} - \nu_{\perp}) \approx 3.10$ kHz]. In this particular case it is straightforward to show that the

Figure 9 Calculated ^{31}P NMR powder spectra of $[\text{HgP}(o\text{-tolyl})_3(\text{NO}_3)_2]_2$ as a function of ΔJ . The direct dipolar coupling constant, $R = 0.64$ kHz, and $(\nu_{\parallel} - \nu_{\perp}) \approx 3.10$ kHz were held constant in each calculation. The central uncoupled ^{31}P NMR spectrum is only shown in the top spectrum; its intensity has been suppressed to emphasize the variations in the satellite subspectra as a function of ΔJ

breadth of each subspectrum is given by

$$\Delta\nu_{\pm m(\text{Hg}-^{199})} = (\nu_{\parallel} - \nu_{\perp}) \pm 3m_{\text{Hg}-^{199}}R_{\text{eff}} \quad (44)$$

Solving equation (44), one obtains $R_{\text{eff}} = -1.10$ kHz. From the known values of $r_{\text{Hg-P}}$ in closely related compounds, $R = 0.64$ kHz; thus $(\Delta J/3) = 1.74$ kHz and $\Delta J = 5.2$ kHz. Note that if the relative signs of R_{eff} and J_{iso} were not known, another acceptable solution would be $R_{\text{eff}} = +1.10$ kHz, hence $\Delta J = -1.38$ kHz. The sensitivity of the ^{31}P NMR spectrum of $[\text{HgP}(o\text{-tolyl})_3(\text{NO}_3)_2]_2$ to ΔJ is illustrated in Figure 9. A complete single crystal ^{31}P NMR study of a closely related compound, $\text{HgP}(\text{cyclohexyl})_3(\text{NO}_3)_2$, has recently been completed.⁵² A typical rotation pattern is shown in Figure 10. Analysis indicates that $R_{\text{eff}} = -1.07$ kHz, leading to comparable values of $\Delta J(^{199}\text{Hg}, ^{31}\text{P})$.⁵² The results of these studies are significant in that they indicate that mechanisms other than the Fermi contact contribute to the $\mathbf{J}(^{199}\text{Hg}, ^{31}\text{P})$ tensor.

For AX spin systems in powder samples, one can also obtain R_{eff} from slow spinning MAS or variable angle spinning NMR studies; however, the errors tend to be large. Therefore, unless R_{eff} is significantly different than R , any estimate of ΔJ may be meaningless.

If a spin- $\frac{1}{2}$ nucleus is coupled to a neighboring quadrupolar nucleus, the spin- $\frac{1}{2}$ MAS NMR lineshape will often exhibit

Figure 10 Plot of $\Delta\nu - J(^{199}\text{Hg}, ^{31}\text{P})_{\text{iso}}$ versus the rotation angle for a single crystal of $\text{HgP}(\text{cyclohexyl})_3(\text{NO}_3)_2$. In this case the rotation axis is approximately perpendicular to the vector $r_{\text{Hg-P}}$ so that the maximum observed variation in frequency (3.21 kHz) is approximately $3R_{\text{eff}}$

residual ‘dipolar splittings’ due to coupling with the quadrupolar nucleus.⁵³ In such cases the magic angle is no longer ‘magic’ because of the breakdown of the high-field approximation. Qualitatively, the Zeeman states of the quadrupolar nuclei are perturbed by the quadrupolar interaction. Thus, the detailed spin- $\frac{1}{2}$ MAS NMR lineshape depends on R_{eff} , B_0 , the nuclear quadrupolar coupling constant, and the orientation of the EFG tensor at the quadrupolar nucleus with respect to R_{AX} . Unless information concerning the EFG tensor at the quadrupolar nucleus is available from independent NMR or NQR studies, analysis of the spin- $\frac{1}{2}$ MAS NMR spectrum will be problematic.

Information concerning ΔJ is also available from NMR studies of solute molecules partially ordered in liquid crystalline solvents; however, again one can only determine R_{AX} . In fact, from such experiments one measures a parameter which is related to $-S_{zz}[R - (\Delta J/3)]$, where S_{zz} is an order parameter, typically of the order of 0.1. In addition, it is necessary to make vibrational corrections and consider solute–liquid crystal solvent interactions. In spite of these problems, reliable values of ΔJ appear to be available for several compounds. For example, for methyl fluoride, $\Delta J(^{19}\text{F}, ^{13}\text{C}) = 404 \pm 31$ Hz, and thus $\Delta J(^{19}\text{F}, ^{13}\text{C})/J(^{19}\text{F}, ^{13}\text{C})_{\text{iso}} = -2.5 \pm 0.2$;⁵⁴ for dimethylmercury, $\Delta J(^{199}\text{Hg}, ^{13}\text{C}) = 855 \pm 14$ Hz, and thus $\Delta J(^{199}\text{Hg}, ^{13}\text{C})/J(^{199}\text{Hg}, ^{13}\text{C})_{\text{iso}} = 1.25 \pm 0.02$.⁵⁵

As mentioned in Section 2, several NMR experiments have been developed to recouple the direct dipolar interaction under conditions of MAS. Although such experiments actually measure R_{eff} , and not R , it is probably reasonable to assume that $(\Delta J/3) \ll R$, if the coupled nuclei are both first row elements (e.g. ^{13}C and ^{15}N), where J_{iso} is probably at least an order of magnitude less than R . Clearly, reliable theoretical calculations could be of value in assessing the validity of this assumption for any given spin pair.

Finally, it is of interest to mention that, several years ago, Andrew and Farnell⁵⁶ investigated the effect of magic angle sample spinning on each of the irreducible tensors which describe the indirect spin–spin coupling tensor [equation (23)]. Of course, MAS does not influence the term $\mathbf{J}\mathbf{1}$; also, the traceless symmetric components do not influence

the MAS spectrum. However, for a homonuclear spin pair, they found that MAS will not necessarily result in a complete averaging of the antisymmetric components of the $\mathbf{J}$ tensor [i.e. components of $\mathbf{J}^{(1)}$ in equation (23)]. The contribution of the antisymmetric components was predicted to be most important when the chemical shift difference between the two coupled spins was very small. Further discussions of the possibility of measuring antisymmetric components of the $\mathbf{J}$ tensor are given in the excellent review by Robert and Wiesenfeld.³⁴ As already mentioned, the antisymmetric components of any indirect spin–spin coupling tensor have not been experimentally characterized.

4 SUMMARY

From the experimental point of view, it is clear that the mathematical properties of the anisotropic indirect $\mathbf{J}$ tensor are analogous to those of the direct dipolar tensor. As a result, it is impossible to measure separately the anisotropic $\mathbf{J}$ tensor and the direct dipolar tensor. Fortunately, for isolated spin pairs in rigid solid samples, the direct dipolar tensor can always be calculated if structural data are available. The most reliable procedure for characterizing $\mathbf{J}$ tensors in the solid state involves single crystal NMR experiments. For solid powder samples the determination of ΔJ is often problematic. The reliability of a powder analysis will always be greatest when: (i) the spin pair of interest lies along a symmetry axis, (ii) J_{iso} is large enough so that the individual subspectra are well resolved, and (iii) R is small or at least comparable to $\Delta J/3$. With the availability of higher sensitivity NMR hardware and advanced single crystal NMR experiments one can hope that more reliable experimental data will become available. In the future, one can also anticipate significant advances in computational techniques, particularly for relatively small molecules involving atoms of the first two rows of the Periodic Table. Unfortunately, these are the systems where it is most difficult to obtain reliable experimental data concerning the anisotropy in the $\mathbf{J}$ tensor. In any case, it is clear that in order to formulate meaningful models relating J couplings to molecular structure, a better understanding of the $\mathbf{J}$ tensor is essential. Obviously, any information that indicates which mechanisms are or are not operative is critically important in leading to a better understanding of J coupling phenomena.

1 INTRODUCTION

Nuclear spin–spin coupling theory has been the subject of several reviews^{1–4} and it has been an annual topic in the Royal Society of Chemistry Reports since 1972.^{5,6} In recent years there has been a renewed interest in the factors controlling heteronuclear spin–spin coupling constants. This is partially attributable to the emergence of multiple pulse techniques for spectral editing as these have produced a wealth of new data.

Like many other topics in NMR an exhaustive review of indirect nuclear spin–spin coupling theory would not be possible within the limitations of this review. Moreover, various aspects of J coupling will appear in other chapters of this monograph. Thus, the scope of this chapter is narrowed to reflect the author's interests in this topic for the past 30 years and to bring some coherence to this material. The coverage of the literature is fairly complete up until the early 1970s. It was at about this time that the FPT-INDO method [finite perturbation theory in the intermediate neglect of differential overlap approximation of self-consistent field molecular orbital (SCF-MO) theory] became generally available and was applied to an enormous number of problems.⁷ In recent years high quality ab initio computations have appeared. These use large basis sets and include extensive correlation corrections applied to both Fermi contact and noncontact mechanisms.^{8–15}

The spin–spin coupling phenomenon quickly emerged as a powerful tool for structural and conformational studies, in part, because of the general applicability of semiempirical methods in reproducing conformational and substituent trends. This is in marked contrast with chemical shielding where the data are even more abundant but semiempirical methods have not been as useful. The first part of this chapter will describe the observation and early interpretation of the spin–spin coupling phenomenon. The second part will present an overview of theoretical descriptions as expressed in density matrix notation and exemplified by semiempirical methods. The final section applies the theory to some organic structural aspects of J coupling, again emphasizing topics of interest to the author.

2 OBSERVATIONS AND EARLY INTERPRETATIONS

The early work in the observation of spin–spin coupling will be described elsewhere in this article and will only be described briefly here. In 1950 the application of spin echo methods to ethanol by Hahn¹⁶ showed ‘slow beats’ in the echo. These were later shown to arise from nuclear spin–spin coupling. Using slow passage conditions, the fine structure in the ¹²¹Sb resonance of a solution of NaSbF₆, which was observed by Proctor and Yu,¹⁷ was thought to arise from the magnetic dipole interaction of the Sb nucleus with the surrounding F nuclei. Gutowsky and McCall¹⁸ also observed fine structure in ³¹P and ¹⁹F spectra. In 1951 there were several other papers on this topic^{19,20} and it was soon concluded that the interaction is independent of the external field but that it does depend on the product of the nuclear spin vectors,^{21–23}

$$\Delta E_{NN'} = h J_{NN'} \mathbf{I}_N \cdot \mathbf{I}_{N'} \quad (1)$$

where $J_{NN'}$ is the nuclear spin–spin coupling constant in hertz. The physical basis for these splittings was disputed until the appearance of papers by Ramsey and Purcell²⁴ and Ramsey.²⁵ They concluded that the interaction arises from ‘the magnetic interaction between each nucleus and the electron spin of its own atom together with the exchange coupling of the electron spin with each other’. In the absence of a magnetic field the spin–spin coupling constant for H₂ is simply the energy difference in hertz between *ortho*- and *para*-hydrogen, e.g. in the absence of a magnetic field it is the difference between the triplet and singlet nuclear spin levels. This is depicted in Figure 1 for a pair of equivalent spin- $\frac{1}{2}$ nuclei. The nuclear Zeeman levels are plotted as a function of the magnetic induction B_0 . The J coupling is taken to be of positive sign if the nuclear spin singlet energy is lower than the triplet energy. This is the case for H₂ because the Fermi contact mechanism (which is dominant) favors the antiparallel arrangement of electron and nuclear spins.

In his 1953 paper Ramsey developed a general formulation for nuclear spin–spin coupling. Equation (1) implies that coupling constant terms will occur in first order perturbation theory if the operators contain the product $\mathbf{I}_N \cdot \mathbf{I}_{N'}$, e.g. the one-electron or orbital diamagnetic term. Contributions will also arise in second order perturbation theory as products of operators ($A_N \cdot \mathbf{I}_N$ and $A_{N'} \cdot \mathbf{I}_{N'}$) containing the two nuclear spins. Ramsey identified three interaction terms of this form, those involving the electron orbital motion with the nuclear spin, the dipolar term involving the electronic spins and the nuclear spins, and the Fermi contact interaction associated with the electronic and the nuclear spins. Ramsey's expression for the (isotropic) Fermi contact term, which is of primary interest here, in Gaussian units is

$$J_{NN'} = -(2/3h) \left(16\pi\beta \frac{\hbar}{3} \right)^2 \gamma_N \gamma_{N'} \sum_{\kappa} ({}^3E_{\kappa} - {}^1E_0)^{-1} \times \left\langle 0 \left| \sum_j \delta(r_{jN}) S_j \right| \kappa \right\rangle \left\langle \kappa \left| \sum_k \delta(r_{kN'}) S_k \right| 0 \right\rangle \quad (2)$$

where $J_{NN'}$ denotes the isotropic coupling between nuclei N and N' having magnetogyric ratios γ_N and $\gamma_{N'}$, respectively. The first summation is over all triplets κ . In the Fermi contact

Figure 1 Energy level diagram for two equivalent spin- $\frac{1}{2}$ nuclei plotted as a function of the magnetic induction B_0 . The coupling constant J is the separation between the nuclear spin singlet and the nuclear spin triplet

operators $\delta(r_{jN})$, for example, denotes the Dirac delta function for electron j at nucleus N , S_j is the electron spin operator for the j th electron, and the summation is taken over all electrons j . Matrix elements connect the singlet states $\langle 0|$ having energy 1E_0 and triplet states $|\kappa\rangle$ having energies $^3E_\kappa$. Equation (2) is the starting point for most discussions of Fermi contact coupling. Ramsey also recognized the tensor nature of the J coupling but for the HD molecule only reported numerical estimates of the *isotropic* terms. Based on the James and Coolidge wavefunction, a value of 40 Hz for the Fermi contact term is in reasonable accord with the experimental value of 42.7 ± 0.7 Hz.²⁶ This also supported arguments for small contributions from noncontact mechanisms. Following speculation that the H–D spin–spin coupling constant had a negative sign,²⁷ Code and Ramsey used molecular beam methods to demonstrate²⁸ that the sign was indeed positive.

Ramsey also made the interesting observation that as the atoms of HD are pulled apart, the denominator in equation (2) approaches zero, a situation in which perturbation theory would not be applicable. Because of a possible relationship to long-range coupling, the dependence of the H–H nuclear spin–spin coupling on $r_{HH'}$ was examined²⁹ using a variational method with Heitler–London wavefunctions including both the electron and nuclear spins. In the dissociation limit the splitting is the electron–nuclear hyperfine coupling. The total electronic spin S cannot be a good quantum number as the molecule dissociates as this would have the contradiction of nuclear spin–spin coupling being nonzero at infinite separation. In the simple Heitler–London picture for which the singlet and triplet energies are asymptotic as $R \rightarrow \infty$, the four

basic product electron spin functions necessarily assume equal weights corresponding to two uncorrelated spins. Had effects as small as the indirect nuclear spin–spin coupling been of interest, these would have been implicit in the detailed work of the Wisconsin group on the H_2 hyperfine splitting.³⁰ The previous reviews^{1–6} should be consulted for references to the many papers concerned with calculation of the HD coupling constant.

Before looking at specific molecular formulations, it will be convenient in the next section to transcribe the various expressions for (Fermi contact) nuclear spin–spin coupling constants into density matrix notation. These techniques will then be used in Sections 3.2–3.4 to discuss the specific quantum mechanical formulations.

3 THEORETICAL FORMULATIONS FOR NUCLEAR SPIN–SPIN COUPLING

3.1 Density Matrix Notation

The density matrix notation adopted here follows that introduced by McWeeny and co-workers.^{31,32} This formalism was used extensively in these laboratories to investigate nuclear spin–spin coupling and a number of other types of NMR parameters. The one-electron *transition density matrix* associated with states Ψ_κ and Ψ_λ is given by

$$\rho_1(\kappa\lambda | 1; 1') = N \int \Psi_\kappa(1, 2, 3, \dots, N) \Psi_\lambda^* \times \Psi_\lambda(1', 2, 3, \dots, N) dr_2 dr_3 \dots dr_N \quad (3)$$

where N is the number of electrons and the integrations are to be taken over the space and spin coordinates r_i of all but one electron. It is sometimes convenient to write the one-electron density matrix in terms of spinless components,

$$\rho_1(\kappa\lambda | 1; 1') = P_1(\kappa\lambda | 1; 1') \alpha(1) \alpha^*(1') + P_1\kappa\lambda | 1; 1') \beta(1) \beta^*(1') \quad (4)$$

from which it follows that for a given state ($\kappa = \lambda$) the diagonal element denotes the probability of finding an electron in volume element at point 1. *Transition spin densities* occur when spin operators are involved and these can be written in terms of the spinless components,

$$Q_1(\kappa\lambda | 1; 1') = P_1(\kappa\lambda | 1; 1') - P_1(\kappa\lambda | 1; 1') \quad (5)$$

For a given state ($\kappa = \lambda$) $Q_1(\kappa\kappa|1;1)$ is just a *spin density* for which integration over all space gives the number of unpaired spins.

From equations (2)–(5) the expression for the Fermi contact (FC) contribution to the isotropic spin–spin coupling is

$$J_{NN'} = -(2h)^{-1} (16\pi\beta\hbar/3)^2 \gamma_N \gamma_{N'} \sum_{\kappa} ({}^3E_\kappa - {}^1E_0)^{-1} \times Q_1(0\kappa_0 | 1_N; 1_N) Q_1(0\kappa_0 | 1_{N'}; 1_{N'}) \quad (6)$$

where $Q_1(0\kappa_0|1_N;1_N)$, for example, denotes the transition spin density evaluated at the position of nucleus N. The advantages of using density matrix notation rather than the integrals in equation (2) are the removal of the spin operators and the ease of writing general density matrix expressions. General density matrix expressions analogous to equation (6) can also easily be written for coupling constant contributions associated with the spin dipolar (SD), and orbital paramagnetic (OP) contributions, as well as the various cross terms.^{33,34}

The initial theoretical work on J coupling invoked the so called ‘average energy approximation’ to simplify the second order expressions. This procedure invokes closure in the second order sum and replaces the excitation energies by an average value ΔE . Although it has long been clear that this procedure is not an approximation in the usual sense of the word,^{35,36} it has led to some very important relationships between J couplings and molecular structures as well as some useful qualitative insights that have permitted correlations of many structural features. The ‘average energy approximation’ was particularly appealing in its very simple relationship to the electron correlation features in n -particle systems.^{32,37,38} In density matrix notation the FC contribution to the spin–spin coupling between nuclei N and N’ at this level of theory is given by³²

$$J_{NN'} = -(3h\Delta E)^{-1}(16\pi\beta\hbar/3)^2\gamma_N\gamma_{N'}Q_c(1_N, 2_{N'}; 1_N, 2_{N'}) \quad (7)$$

where $Q_c(1_N, 2_{N'}; 1_N, 2_{N'})$ denotes a two-electron spin density (or spin coupling matrix) evaluated at the positions of the coupled nuclei, and ΔE is an ‘average excitation energy’. The usual state labels of density matrix notation are not used here because only the ground state wavefunction is involved. The two-electron spin density matrix is related to the two-electron spinless components of the density matrix,

$$Q_c(1, 2; 1', 2') = 3[P_2(1, 2; 1', 2')^{\alpha\alpha\alpha\alpha} - P_2(1, 2; 1', 2')^{\alpha\beta\alpha\beta}] \quad (8)$$

where the first term on the right denotes the simultaneous probability of finding the two electrons with α spin in differential volume elements at points 1 and 2, and the second term denotes the corresponding probability for electrons of opposite spin. We now look at some important implications of these relationships. The spinless components in equation (8) are related to the one-particle spinless density matrix components in equation (4) and correlation functions for electrons of the same and opposite spins,

$$P_2(1, 2; 1, 2)^{\alpha\alpha\alpha\alpha} = P_1(1; 1)^{\alpha\alpha}P_1(2; 2)^{\alpha\alpha}[1 + f(1, 2)^{\alpha\alpha}] \quad (9)$$

$$P_2[(1, 2; 1, 2)]^{\alpha\beta\alpha\beta} = P_1(1; 1)^{\alpha\alpha}P_1(2; 2)^{\beta\beta}[1 + f(1, 2)^{\alpha\beta}] \quad (10)$$

where $f(1, 2)^{\alpha\alpha}$ and $f(1, 2)^{\alpha\beta}$ denote correlation functions for electrons of the same and of opposite spins, respectively. The Pauli Exclusion Principle requires that as the coordinates of particle 2 approach those of particle 1,

$$f(1, 2)^{\alpha\alpha} \rightarrow -1 \quad \text{and} \quad f(1, 2)^{\alpha\beta} \rightarrow -1 \quad (10a)$$

corresponding to 100% negative correlation which prevents particles of like spin being found at the same point in space.³¹

Since essentially all of the molecules of interest are in singlet ground states

$$P_1(1; 1)^{\alpha\alpha} = P_1(2; 2)^{\beta\beta} = (\frac{1}{2})P_1(1; 1) \quad (11)$$

so that both the two-electron spin density matrix and the nuclear spin–spin coupling are proportional to the differences in the correlation functions for electrons of the same and opposite spins,

$$Q_c(1, 2; 1, 2) = (\frac{3}{4})P_1(1; 1)P_1(2; 2)[f(1, 2)^{\alpha\alpha} - f(1, 2)^{\alpha\beta}] \quad (12)$$

At this level of theory the various bond orders provide estimates for the differences in the correlation functions in equation (12).

3.2 Early Theory

The recognition of the spin coupling phenomenon quickly led to theoretical discussion using the Heitler–London formulation.³⁹ It also provided an explanation for linewidths in solids which were larger than could be accounted for on the basis of the direct dipole–dipole interactions.^{40,41}

3.2.1 Molecular Orbital Methods

In the period 1955–1957 McConnell considered the J coupling problem from several points of view including a molecular orbital description,⁴² a Dirac vector model,⁴³ and a spin-exchange model.^{44,45} The MO model was used by Saika⁴⁶ to investigate the J coupling in ammonia. On the basis of MO results in which interproton spin–spin coupling constants were proportional to the square of the MO bond order, McConnell speculated that interproton coupling constants were probably all positive in sign.⁴⁷ In the light of subsequent sign measurements, a formulation was used to rationalize the negative $J(\text{H}, \text{H}')$ in aromatic systems.⁴⁸ During this period Pople related the orbital contributions to nuclear spin–spin coupling to the anisotropy of the magnetic screening.⁴⁹

In single determinant Hartree–Fock theory the correlation function for electrons of opposite spins in equation (12) vanishes identically, and assuming that the molecule has a singlet ground state,

$$Q_c(1, 2; 1, 2) = (\frac{3}{4})P_1(1; 1)P_1(2; 2)f(1, 2)^{\alpha\alpha} \quad (13)$$

which is negative because the correlation function $f(1, 2)^{\alpha\alpha}$ is inherently negative (it is zero if the electrons are uncorrelated).

Expanding a Slater determinant via Laplace’s development leads to an expression for the two-particle density matrix in terms of the Fock–Dirac density matrix $\rho_1(1;1')$,³²

$$\rho_2(1, 2; 1', 2') = \rho_1(1; 1')\rho_1(2, 2') - \rho_1(1; 2')\rho_1(2; 1') \quad (14)$$

Rewriting the one-particle density matrices in terms of the spinless components provides an expression for the two-electron spinless components,

$$P_2(1, 2; 1', 2') = P_1(1; 1')P_1(2, 2') - P_1(1; 2')P_1(2; 1') \quad (15)$$

$$P_2(1, 2; 1', 2') = P_1(1; 1')P_1(2; 2') \quad (16)$$

From equation (8) the spin coupling function can, therefore, be written in terms of the off-diagonal elements of the one-particle density matrix

$$Q_c(1, 2; 1, 2) = -(\frac{3}{4})P_1(1; 2)P_1(2; 1) \quad (17)$$

where the off-diagonal elements of the one-particle density matrix can be written in terms of the molecular orbitals

$$\begin{aligned} P_1(1; 2) &= \sum_i n_i \chi_i(1)\chi_i^*(2) = \sum_{\mu\nu} \sum_i n_i c_{i\mu} c_{i\nu}^* \phi_\mu(1)\phi_\nu^*(2) \\ &= \sum_{\mu\nu} \eta_{\mu\nu} \phi_\mu(1)\phi_\nu^*(2) \end{aligned} \quad (18)$$

In the i th molecular orbital $c_{i\mu}$ and $c_{i\nu}$ are the coefficients of orbitals μ and ν , respectively, n_i is the occupation number, and $\eta_{\mu\nu}$ is the bond order between orbitals μ and ν as defined by Coulson and Longuet-Higgins,⁵⁰

$$\eta_{\mu\nu} = \sum_i n_i c_{i\mu} c_{i\nu}^* \quad (19)$$

Substituting equation (18) into equation (17), one sees that at this level of MO theory the coupling constant is proportional to the square of the bond order. This is awkward, not only because of the single sign problem noted above, but also because this type of bond order vanishes for even alternant systems if orbitals μ and ν are in the same subset.⁵⁰ Of course, this result is not consistent with a large number of examples of sizable spin-spin coupling constants of either sign for atoms separated by an even number of bonds. These problems can be circumvented in alternant MO methods³⁸ in which both types of correlation are included in an easily visualized way. For the specific case of a molecule with two electrons, e.g. H_2 $P_2(1, 2; 1, 2) = 0$, so the coupling constant is proportional to

$$\begin{aligned} Q_c(1, 2; 1, 2) &= -3P_2(1, 2; 1, 2) \\ &= -3P_1(1; 1)P_1(2, 2)[1 + f(1, 2)] \end{aligned} \quad (20)$$

Since $f(1, 2) = 0$ at the Hartree-Fock level, equation (13) becomes simply

$$Q_c(1, 2; 1, 2) = -(\frac{3}{4})P_1(1; 1)P_1(2, 2) \quad (21)$$

For a two-electron system in terms of the occupied MO χ the diagonal element is simply

$$P_1(1; 1) = 2\chi(1)\chi^*(1') \quad (22)$$

Taking χ to be a linear combination of atomic orbitals ϕ_μ and ϕ_ν , associated with nuclei N and N', then

$$\begin{aligned} P_1(1; 1') &= \phi_\mu(1)\phi_\mu^*(1') + \phi_\nu(1)\phi_\nu^*(1') \\ &\quad + \phi_\mu(1)\phi_\nu^*(1') + \phi_\nu(1)\phi_\mu^*(1') \end{aligned} \quad (23)$$

Neglecting terms like $\phi_\mu(1_N)\phi_\nu^*(1_N)$ in comparison with terms like $\phi_\mu^2(1_N)$, it then follows from equations (7) and (22) that the directly bonded coupling constant expression is

$$J_{NN'} = (h\Delta E)^{-1}(16\pi\beta\hbar/3)^2\gamma_N\gamma_{N'}\phi_\mu^2(1_N)\phi_\nu^2(1_{N'}) \quad (24)$$

Substitution of the form for a hybrid orbital for one or both of ϕ_μ and ϕ_ν where ϕ_μ is of the form

$$\phi_\mu = as_\mu + (1 - a^2)^{1/2}p_{\sigma\mu} \quad (25)$$

where s_μ and $p_{\sigma\mu}$ denote 2s and 2p atomic orbitals on atom μ and a^2 is the s character. The resulting equation relates directly bonded, e.g. $^{13}C-H$ and $^{13}C-^{13}C$ coupling constants to the s characters at the carbon atoms.⁵¹⁻⁵³ Equation (25) neglects a factor of $(1 + S)^{-2}$, where S is the overlap integral between bonded orbitals ϕ_μ and ϕ_ν . By means of an alternant molecular orbital method it was noted³⁸ that *the neglect of overlap compensates to some extent for the neglect of electron correlation!*

3.2.2 Valence Bond (VB) Methods

These methods were used extensively in the early work in nuclear spin-spin coupling.⁵⁴⁻⁷¹ Certainly, the most widely known application is that for the angular dependence of the vicinal H-H coupling constants in ethane.⁵⁸ Since the VB method had an important impact on the development of spin-spin coupling theory, its application in conformational analyses, and some intuition regarding the electronic factors leading to the phenomenon, a brief review seems appropriate here. Even though VB concepts are closely tied to chemists' ideas of formulas, resonance, etc., the quantum mechanical methods are unfamiliar to many chemists. The derivation of VB coupling constant expressions demonstrates the simplicity provided by the density matrix formalism. In the simple VB method the singlet ground state wavefunction $^1\Psi_0$ is written as a linear combination of independent, nonpolar VB structures $^1\Phi_j$,⁷²

$$^1\Psi_0 = \sum_j c_j ^1\Phi_j \quad (26)$$

The $^1\Phi_j$ can be constructed formally by placing $2n$ points on the circumference of a circle and then drawing all possible structures which have all of the points connected, but in which no two lines cross. For example, depicted in Figure 2(a) are the two independent, singlet VB structures $^1\Phi_1$ and $^1\Phi_2$. These are useful for investigating geminal, vicinal, and long range H-H coupling as described simply by two C-H bonds as depicted in Figure 2(b). The perfect pairing structure is that in which there are covalent bonds between the carbon hybrid orbitals and the hydrogenic 1s atomic orbitals $c-h$ and $c'-h'$. The nonperfect pairing structure is of

Figure 2 (a) Valence bond singlet structures for a system of four electrons associated with two C–H bonds. Structure ${}^1\Phi_1$ is the perfect pairing structure and ${}^1\Phi_2$ is the non-perfect pairing structure. (b) Schematic representations of four electron fragments for (i) geminal coupling in a CH_2 moiety, (ii) vicinal coupling in an ethanic moiety, and (iii) long-range coupling in a propanic moiety

higher energy since it involves breaking the two C–H bonds and forming bonds between h and h' and c and c' . In the VB formulation nonvanishing H–H coupling arises from the contributions of ${}^1\Phi_2$ to the ground state wavefunction. Matrix elements entering the secular determinant associated with equation (26) are constructed by superimposing the various structures.⁷³ The matrix elements are written as a sum of terms involving Coulomb and exchange integrals multiplied by a function which is determined by superimposing the VB structures. For a $2n$ electron system the coefficients of the Coulomb integrals are $(\frac{1}{2})^{n-i_{jl}}$ where i_{jl} is the number of islands (closed polygons) which occur in the superposition diagram of structures j and l . The coefficients of the exchange integrals are $(\frac{1}{2})^{n-i_{jl}} f_{jl}^{\mu\nu}$ where $f_{jl}^{\mu\nu}$ assumes the values 1, -2 , and $-\frac{1}{2}$ depending on whether orbital μ and ν are in the same island separated by an odd number of bonds, or an even number of bonds, or are in different islands, respectively. The two-electron density matrix follows directly from the expression for the ground state energy,

$$P_2(1, 2; 1', 2') = \sum_{j,l} c_j c_l \left(\frac{1}{2} \right)^{n-i_{jl}} \sum_{\mu,\nu} [\phi_\mu(1)\phi_\nu(2)\phi_\mu(1')\phi_\nu(2') + f_{jl}^{\mu\nu} \phi_\mu(1)\phi_\nu(2)\phi_\nu(1')\phi_\mu(2')] \quad (27)$$

where c_j is the coefficient of the j th VB structure, and ϕ_μ and ϕ_ν are atomic orbitals. The spin–spin coupling function is obtained from equations (7) and (8) and the spinless components of $P_2(1, 2; 1', 2')$,^{32,74}

$$Q_c(1, 2; 1', 2') = -\left(\frac{1}{2}\right) \sum_{j,l} c_j c_l \left(\frac{1}{2}\right)^{n-i_{jl}} \times \sum_{\mu,\nu} [(1 + 2f_{jl}^{\mu\nu})\phi_\mu(1)\phi_\nu(2)\phi_\mu(1')\phi_\nu(2') + (2 + f_{jl}^{\mu\nu})\phi_\mu(1)\phi_\nu(2)\phi_\nu(1')\phi_\mu(2')] \quad (28)$$

Equation (28) can immediately be rewritten in terms of the Penney–Dirac bond orders $p_{\text{PD}}(\mu, \nu)$,

$$Q_c(1, 2; 1', 2') = -\left(\frac{3}{2}\right) \sum_{\mu,\nu} \{p_{\text{PD}}(\mu, \nu)\phi_\mu(1)\phi_\nu(2)\phi_\mu(1')\phi_\nu(2') + (1')\phi_\nu(2') + \left(\frac{1}{2}\right)[1 + p_{\text{PD}}(\mu, \nu)]\phi_\mu(1)\phi_\nu(2)\phi_\nu(1')\phi_\mu(2')\} \quad (29)$$

where⁷⁵

$$p_{\text{PD}}(\mu, \nu) = \left(\frac{1}{3}\right) \sum_{j,l} c_j c_l \left(\frac{1}{2}\right)^{n-i_{jl}} (1 + 2f_{jl}^{\mu\nu}) \quad (30)$$

Neglecting two-center overlap terms of the type $\phi_\mu(1_N)\phi_\nu(1_N)$ in equation (27) shows that the nuclear spin–spin (FC contribution) coupling is linearly related to the Penney–Dirac bond order $p_{\text{PD}}(\mu, \nu)$.⁶⁶ Consider several situations for H–H coupling represented by the two C–H bonds in Figure 2(b). Depending on whether the hybrid orbitals c and c' constitute (i) a geminal pair, (ii) a vicinal pair, or (iii) are hybrid carbon orbitals separated by two or more bonds, these structures provide a useful, but simplistic, representation of the corresponding coupling situations. Note that the PD bond order $p_{\text{PD}}(h, h')$ has no contribution from the perfect pairing structure [see Figure 2(a)] because $f_{11}^{hh'} = -\frac{1}{2}$ in equation (30). However, in the superposition diagram for ${}^1\Phi_1$ and ${}^1\Phi_2$, $f_{12}^{hh'} = 1$ leading to a nonvanishing contribution to $p_{\text{PD}}(h, h')$. Using perturbation theory $c_1 \approx 1$,^{54,74} hence

$$c_2 \approx \left(\frac{1}{2}\right) \left[\frac{K(h, h') + K(c, c') - K(c, h') - K(c', h)}{K(c, h) + K(c', h') - K(c, c') - K(h, h')} \right] \quad (31)$$

where $K(\mu, \nu)$ is a two-center exchange integral associated with orbitals ϕ_μ and ϕ_ν ,

$$K(\mu, \nu) = \iint \phi_\mu(1)\phi_\nu(2)[(R_{ab})^{-1} + (r_{12})^{-1} - (r_{1b})^{-1} - (r_{2a})^{-1}]\phi_\nu(1)\phi_\mu(2) \, d\tau_1 \, d\tau_2 \quad (32)$$

From equation (30) the PD bond order associated with the hydrogens is simply,

$$p_{\text{PD}}(h, h') = c_1 c_2 + c_2^2 \approx c_1 c_2 \approx c_2 \quad (33)$$

Since $c_2 \ll c_1 \approx 1$ for saturated systems, in this simple model the coupling constant is proportional to the contribution of the nonperfect pairing structure to the ground state wavefunctions,

and it related to the exchange integrals in equation (31). As the numerator and any one of the exchange integrals can be of either sign, the Penney–Dirac bond orders and coupling constants can be either positive or negative. This is a more plausible result than the quadratic dependence on the MO bond order, which occurs because of the very different ways in which electron correlation appears in these two methods! Because of the extreme importance of electron correlation effects for nuclear spin–spin coupling, the early successes of valence bond methods compared with simple MO methods should come as no surprise.

At an early stage in the development of NMR this simple VB theory qualitatively explained a number of aspects of interproton coupling: geminal H–H coupling is quite sensitive to exchange integral cancellation in the numerator of equation (31). In comparison with vicinal H–H coupling constants, geminal H–H coupling constants are very sensitive to H–C–H angles, substituent and solvent effects. The original VB calculations for vicinal H–H coupling constants in an ethane fragment were based on a six-electron fragment for the ethane molecule. However, all of the important aspects are implicit in the four-electron model described herein. In the original paper⁵⁸ describing the dihedral angle dependence of vicinal H–H coupling constants, the only necessary nonbonded exchange integral was $K(c, c')$ occurring in the numerator of equation (29). The hybrid orbitals c and c' are depicted in Figure 2(b). The most general form of a, e.g., carbon hybrid orbital ϕ_μ can be written in terms of atomic s- and p-type atomic orbitals, the angle θ_μ that the hybrid orbital makes with the z axis, and the dihedral angle φ about the z axis,

$$\phi_\mu = a_\mu s_\mu + (1 - a_\mu^2)^{1/2} (\cos \varphi \sin \theta_\mu p_{x\mu} + \sin \varphi \sin \theta_\mu p_{y\mu} + \cos \theta_\mu p_{z\mu}) \quad (34)$$

where s_μ , $p_{x\mu}$, $p_{y\mu}$, and $p_{z\mu}$ denote the 2s and 2p atomic orbitals associated with the μ th hybrid orbital, and a_μ is defined such that a_μ^2 is the s character of the hybrid orbital. If equation (4) is specialized, for example, to tetrahedral hybrids with appropriate bond angles and a single dihedral angle φ , substitution of equation (34) into equation (32) gives the mathematical form for the vicinal exchange integral

$$K(c, c') = A \cos^2 \varphi + B \cos \varphi + C \quad (35)$$

From equations (28)–(31), (33) and (7) this will also be the approximate form for dependence of vicinal coupling constants on dihedral angles.

This simple, qualitative VB model can be extended to systems which have more than four electrons by means of ‘fragment’ bond orders of the type given in equations (31) and (33). The fragment bond order $p^0(r, s)$ associated with bonds r – r' and s – s' is

$$p^0(r, s) = \left(\frac{1}{2}\right) \left[\frac{K(r, s) + K(r', s') - K(r, s') - K(r', s)}{K(r, r') + K(s, s') - K(r, s) - K(r', s')} \right] \quad (36)$$

Consider the calculation of the PD bond order $p_{PD}(h, h')$ for the molecular system depicted in Figure 3. In addition to the two C–H bonds there are N bond pairs $(t-t')$. The Penney–Dirac bond orders can be determined from the

Figure 3 Schematic representations of a four-electron fragment plus n -bonds $(t-t')_j$

coefficients obtained by perturbation theory. Up to second order the bond order associated with the two hydrogens is written in terms of the fragment bond orders. An approximate expression is⁷⁴

$$p_{PD}(h, h') = p^0(h, h') + \left(\frac{3}{2}\right) \sum_j p^0(h, t_j) p^0(t'_j, h') \quad (37)$$

where each of the fragment bond orders is of form of equation (36). The first term on the right hand side of equation (37) has been associated with a *direct* coupling mechanism and the second with the many possible *indirect* coupling mechanisms.⁷⁴ It seems likely that the widely but undefined terms ‘through space’ and ‘through bond’ have led to substantial confusion regarding the factors responsible for spin–spin coupling. Additional relationships among the bond order expressions are as follows:

$$p^0(h, h') = p^0(c, c') = -p^0(c, h') = -p^0(h, c') \quad (38)$$

These equations provide a basis for interrelating the various coupling constants and the simple VB bond order model provides a qualitative basis for interpreting a wide variety of substituent and conformational effects.^{74,76–80}

3.3 Sum-Over-States Methods

3.3.1 Molecular Orbital Descriptions

Where the ground state wavefunction is given as an antisymmetrized product of molecular orbitals,

$$^1\Psi_0 = \mathcal{A}[\chi_1(1)\overline{\chi_1(2)}\chi_2(3)\dots\chi_i(k)\overline{\chi_i(k+1)}\dots] \quad (39)$$

and triplet state wavefunctions are produced by exciting an electron from the i th occupied MO to the j th unoccupied MO,

$$^3\Psi_{km} = \mathcal{A}[\chi_1(1)\overline{\chi_1(2)}\chi_2(3)\dots\chi_i(k)\dots\chi_j(k+1)\dots] \quad (40)$$

In equation (40) electrons k and $k+1$ have parallel spins and $m = +1, 0$, and -1 . The transition density matrix associated with the ground state and $m = 0$ components of the triplet levels is given from equations (3), (32) and (33),

$$\begin{aligned} \rho_1(0\kappa_0 | 1; 1') &= 2 \int \chi_i(1)\chi_i(2)(1/\sqrt{2})[\alpha(1)\beta(2) - \beta(1)\alpha(2)] \\ &\quad \times (1/\sqrt{2})[\chi_i^*(1')\chi_j^*(2) + \chi_j^*(1')\chi_i^*(2)] \\ &\quad \times (1/\sqrt{2})[\alpha^*(1')\beta^*(2) + \beta^*(1')\alpha^*(2)] dr_2 \quad (41) \end{aligned}$$

Integration over the space and spin coordinates of electron 2 yields the transition density matrix

$$\rho_1(0\kappa_0 | 1; 1') = -(1/\sqrt{2})\chi_i(1)\chi_j^*(1')[\alpha(1)\alpha^*(1') - \beta(1)\beta^*(1')] \quad (42)$$

which defines the spinless components. These provide an expression for the transition spin density matrix

$$Q_1(0\kappa_0 | 1; 1') = -\sqrt{2}\chi_i(1)\chi_j^*(1') \quad (43)$$

Substituting equation (43) into equation (6) leads to an expression for the FC contribution

$$J_{NN'} = -h^{-1}(16\pi\beta\hbar/3)^2\gamma_N\gamma_{N'} \sum_{i,j} (\epsilon_j - \epsilon_i)^{-1} \times \chi_i(1_N)\chi_j^*(1_N)\chi_i(1_{N'})\chi_j^*(1_{N'}) \quad (44)$$

where the sum is over the occupied and unoccupied MOs i and j , respectively. Expanding the MOs as a linear combination of atomic orbitals and neglecting contributions other than the s-type orbitals centered on atoms N and N', this becomes

$$J_{NN'} = -h^{-1}(16\pi\beta\hbar/3)^2\gamma_N\gamma_{N'} \sum_{i,j} (\epsilon_j - \epsilon_i)^{-1} c_{i\mu}c_{j\nu}c_{i\nu}c_{j\mu} \times \phi_\mu^2(1_N)\phi_\nu^2(1_{N'}) \quad (45)$$

where orbitals ϕ_μ and ϕ_ν are associated with nucleus N and N', respectively. Equation (44) is more conveniently written in the form

$$J_{NN'} = -(4h)^{-1}(16\pi\beta\hbar/3)^2\gamma_N\gamma_{N'}\phi_\mu^2(1_N)\phi_\nu^2(1_{N'})\pi_{\mu\nu} \quad (46)$$

where the mutual atom–atom polarizability $\pi_{\mu\nu}$ is given by⁵⁰

$$\pi_{\mu\nu} = -4 \sum_{i,j} (\epsilon_j - \epsilon_i)^{-1} c_{i\mu}c_{i\nu}c_{j\mu}c_{j\nu} \quad (47)$$

This equation has been used extensively to calculate contact contributions to spin–spin coupling constants and to rationalize substituent trends. Pople and Santry used this formulation and an independent electron MO model⁸¹ to investigate spin–spin coupling constants in hydrocarbons. Perturbation theory was used to relate the mutual atom–atom polarizabilities in equation (47) to the off-diagonal elements of the Hamiltonian.⁸¹ These techniques were extended by several groups to investigate J couplings in a variety of situations.^{82–86} Murrell and Gil also used a perturbation approach but for hydrocarbons included the additional integrals which involve the hydrogens.⁸² This formulation was also used with a variety of different types of approximate methods, including extended Hückel,^{87–91} complete neglect of differential overlap (CNDO),⁹² INDO,⁹³ and wavefunctions⁹⁴ based on a modified Mulliken approximation.⁹⁵

The Pople–Santry sum-over-states formulation (usually with a modified denominator to account for triplet energies) or the finite perturbation theory (FPT) method described in the next section was used for ab initio calculations.^{33,96–102} The results were unsatisfactory. For example, nonempirical

results with SCF wavefunctions (with the exception of values for HFC=O) led to coupling constants which were 2–4 times too large in magnitude.¹⁰²

In a number of cases molecular symmetry has been exploited in the sum-over-states formulation to provide elegant descriptions of substituent effects. These include geminal H–H,^{103,104} long range H–H,^{105,106} and coupling in ethylenic and aromatic systems.¹⁰⁷ The Pople–Santry method⁸¹ was also used to investigate the importance of noncontact mechanisms, e.g. F–F coupling constants,^{108,109} and ¹³C–¹³C coupling constants.¹¹⁰

Hiroike¹¹¹ noted that the simple VB and MO methods based on equation (46) without configuration interaction (CI) represent different contributions to the spin–spin coupling constant. In fact, for the case of long range H–H coupling over four bonds it was found that the sum of the two results gives a much better representation than either of the MO or VB results.¹¹²

3.3.2 Valence Bond Sum-Over-Triplet Description

In the VB sum-over-triplet level scheme from these laboratories,^{113,114} the ground state wavefunction is written as before, and the wavefunctions for the manifold of triplets are written,

$${}^3\Psi_K = \sum_l c_{kl} {}^3\Phi_l \quad (48)$$

where for a system of $2n$ electrons ${}^3\Phi_l$ denotes a set of $3[(2n)/(n+2)(n-1)!]$ linearly independent, nonpolar triplet canonical structures. These structures can most easily be obtained from the usual Rumer structures according to a scheme devised by McLachlan.¹¹⁵ For the system of two c – h bonds these structures are depicted in Figure 4. The transition spin densities follow from equations (3)–(5), (26) and (48)

$$Q_1(0\kappa_0 | 1; 1') = \sum_{j,l} c_j c_{kl} \left(\frac{1}{2}\right)^{n-i_{jl}} \sum_{\mu} \phi_{\mu}(1)\phi_{\mu}^*(1') f_{jl}^{\mu} \quad (49)$$

where in the superposition diagrams of the singlet and triplet canonical structures, i_{jl} is the number of islands and $f_{jl}^{\mu} = +1$ or -1 if orbital ϕ_{μ} is part of an island which contains a broken bond and is in the even or odd subset respectively.

The VB method with a sum-over-triplets has not been extensively applied. Even in its semiempirical form, a

Figure 4 Valence bond triplet structures for a system of four electrons associated with two C–H bonds

molecule with $2n$ electrons requires the calculation of a ground state wavefunction having $[(2n!/n!(n+1)!)]$ nonpolar singlet structures and $3[(2n!)/(n+2)!(n-1)!]$ nonpolar triplets. A general scheme for calculating coupling constants, which was developed within the framework of the generalized product approximation, permitted calculations of a large number of coupling constants via VB and other methods.^{116–118} Since correlation effects are implicit in the ground state and triplet state VB functions, it is not surprising that it provides an excellent semiempirical description of nuclear spin–spin coupling.

3.3.3 The Generalized Product Approximation with Intergroup Configuration Interaction

This method provides a generalization of existing methods for FC spin–spin coupling in terms of the second order perturbation approaches of equations (2) and (6). The recognition of distinct groups in the molecule such as bonds and π -electron systems, permits a simplification of the discussion of many-electron systems.³² However, for cases of more than one group, an adequate description of spin coupling requires intergroup CI. Group function methods have proved to be a convenient framework for investigating, e.g. long range coupling transmitted via the π -electron systems.^{119–126} Although not originally cast in terms of density matrix notation, the various formulations for π -electron contributions to spin–spin coupling can conveniently be described by the generalized product approximation with intergroup CI.¹²⁷ For a molecular system in which distinct groups A , B , C , etc. are recognized, a single configuration wavefunction is of the form

$${}^1\Phi_0 = \mathcal{A}[{}^1\phi_{A0}(1, 2, \dots, N_A) {}^1\phi_{B0}(N_A + 1, N_A + 2, \dots, N_A + N_B) \dots] \quad (50)$$

where $\mathcal{A}$ is an operator which gives a normalized, antisymmetric wavefunction, and ${}^1\phi_{R0}$ is the lowest energy singlet state wavefunction for the N_R electron group R . Triplet wavefunctions ${}^3\phi_{Rm}$ ($m = +1, 0, -1$) are obtained by exciting group R to the r_m th triplet state,

$${}^3\Phi_{Rm} = \mathcal{A}[{}^1\phi_{A0} {}^1\phi_{B0} \dots {}^3\phi_{Rm} \dots] \quad (51)$$

In the single configuration approximation, transition spin densities between ${}^1\phi_0$ and ${}^3\phi_{Rm}$ only arise for group R ,

$$Q_1(0\kappa_0 | 1; 1') = Q_1(0r_m | 1; 1') \quad (52)$$

Therefore, the only nonzero contributions to the nuclear spin coupling constant from equation (6) would be those for which electrons in group R have nonvanishing densities at nuclei N and N' . Presumably, this would only be the trivial situation in which there was only one group describable by the previous formulations. As a more interesting alternative, consider configurational mixing between the ground state and those singlets ${}^1\Phi_{RS}$ produced by exciting two groups R and S to triplets and spin coupling to a singlet,

$${}^1\Psi_0 = c_0 {}^1\Phi_0 + \sum_{RS} c_{rs} {}^1\Phi_{RS} \quad (53)$$

where

$${}^1\Phi_{RS} = 3^{-1/2}(\Phi_{Rr+1} S_{s-1} - \Phi_{Rr0} S_0 + \Phi_{Rr-1} r_{+1}) \quad (54)$$

in which

$$\Phi_{Rr+1} S_{s-1} = \mathcal{A}({}^3\phi_{Rr+1} {}^3\phi_{Ss-1}) \quad (55)$$

The summation in equation (53) is over all of the triplets. If one considers all possible coupling schemes, this would eventually produce all of the singlet, nonpolar VB structures. Furthermore, in the triplet manifold configurational mixing occurs, for example, between a given triplet and those obtained by exciting all the other groups to triplets,

$${}^3\Psi_{\rho_0} = \sum_{r_0} c_{\rho_0 r_0} {}^3\Phi_{Rr_0} + \sum_{\rho_0 s_0} c_{\rho_0 s_0} {}^3\Phi_{Ss_0} \quad (56)$$

The transition spin densities which enter the FC coupling expression in equation (6) follow from equation (3), equations (53) and (56). The coefficients entering equations (53) and (56) and the energies appropriate to equation (6) can easily be obtained directly by solving the secular determinants^{116–118} or by means of perturbation theory.^{127,128}

3.4 Coupled Hartree–Fock/Finite Perturbation Descriptions

One of the most widely used methods for J coupling makes use of coupled Hartree–Fock theory. In coupled Hartree–Fock theory the nuclear perturbation of the electronic system is included in the Hamiltonian,

$$\mathcal{H} = \mathcal{H}_0 + \mathbf{A}_N \cdot \boldsymbol{\mu}_N + \mathbf{A}_{N'} \cdot \boldsymbol{\mu}_{N'} \quad (57)$$

and the Hartree–Fock equations are solved in the usual Roothaan type of formulation. Some of the previous equations, e.g. equation (44) conform to one type of uncoupling scheme for the Hartree–Fock equations.¹²⁹ There are several ways to perform calculations of J couplings that are equivalent to the coupled Hartree–Fock method. The most widely used is the FPT of Pople and co-workers.^{7,130}

Expanding the energy in a Taylor's series over the magnetic moments, then the coupling constant is proportional to the second derivative of the energy,

$$J_{NN'} \propto \left[\frac{\partial^2 E(\mu_N, \mu_{N'})}{\partial \mu_N \partial \mu_{N'}} \right]_{\mu_N = \mu_{N'} = 0} \quad (58)$$

From the Hellman–Feynman theorem the authors⁷ further showed that

$$J_{NN'} \propto \left[\frac{\partial}{\partial \mu_{N'}} \langle \Psi(\mu_{N'}) | \mathbf{A}_N | \Psi(\mu_{N'}) \rangle \right]_{\mu_{N'} = 0} \quad (59)$$

where the matrix elements can be written in terms of the spin density matrix,

$$\rho = P_1 \begin{smallmatrix} \alpha & \alpha \\ 1 & 1 \end{smallmatrix} - P_1 \begin{smallmatrix} \beta & \beta \\ 1 & 1 \end{smallmatrix} \quad (60)$$

For FC coupling it follows from equation (59) that

$$\langle \Psi(\mu_{N'}) | A_N | \Psi(\mu_N) \rangle = (8\pi\beta/3) \sum_{\mu\nu} \rho_{\mu\nu}(\mu_N) \langle \phi_\mu | \delta(r_N) | \phi_\nu \rangle \quad (61)$$

where μ and ν denote atomic orbitals and it is assumed as usual that matrix elements of $\delta(r_N)$ in equation (61) vanish except for s-type orbitals on N.

The self-consistent perturbation theory (SCPT) method was introduced by Blizzard and Santry¹³¹ as a less computationally demanding alternative to the FPT approach. An alternative method makes use of the first-order polarization propagator (FOPPA).¹³² This has been used extensively by Engelmann and Contreras¹³³ and co-workers. Applications of coupled Hartree–Fock methods including FPT, SCPT, and FOPPA formulations are far too numerous to be included here. Since noncontact mechanisms have not otherwise been emphasized here, mention should be made of the studies of $^1J(\text{C},\text{C})$ ^{134,135} coupling, those involving second row atoms,^{135,136} and nonempirical calculations.^{137–140} Within the semiempirical INDO framework, the FOPPA method (with respect to the inclusion of multicenter integrals)¹⁴¹ leads to values of FC, OP, and SD contributions which are generally in accord with the nonempirical results.

A comparison of coupled Hartree–Fock methods with sum-over-states approaches indicated that the FPT method also introduces doubly excited states in a restricted way and should give quite different results when correlation is important for the unperturbed wavefunction.^{142,143}

4 APPLICATIONS TO SPECIFIC COUPLING SITUATIONS

To examine the topic of scalar coupling from a qualitative point of view, it is often convenient to work with a simple VB bond order picture.⁷⁴ An alternative model, which leads to similar conclusions makes use of a MO model in which the MOs χ_i are written as a linear combination of hybrid type orbitals ϕ_μ (HTOs),

$$\chi_i = \sum_{\mu} c_{i\mu} \phi_{\mu} \quad (62)$$

where the ϕ_μ can be written in terms of atomic s- and p-type atomic orbitals as in equations (25) or (34). In the basis set of HTOs the expression for the FC contribution to $J_{NN'}$ is identical to the one obtained by Pople and Santry.⁸¹ The nuclear spin–spin coupling constant is proportional to the mutual atom–atom polarizability in equations (46) and (47). For geminal, vicinal coupling, or long-range H–H coupling perturbation theory can be used to relate $\pi_{hh'}$ to the off-diagonal elements of the Hamiltonian,^{81–86}

$$\pi_{hh'} = (-5\beta_{cc'}^2 - 2\beta_{hh'}^2 + 4\beta_{hc'}^2 + 2\beta_{cc'}\beta_{hh'})/(16\beta^3) \quad (63)$$

where $\beta_{cc'}$, for example, is the matrix element of the Hamiltonian operator between HTOs c and c' , which are

directed toward hydrogenic orbitals h and h' as in Figure 2(b).

$$\beta_{cc'} = \langle \phi_c | \mathcal{H} | \phi_{c'} \rangle \quad (64)$$

The off-diagonal element beta; in the denominator of equation (63) corresponds to an average of those between orbitals which are bonded in the primary valence structure. As a consequence of the assumptions which are implicit in the expressions for $\pi_{hh'}$, and others associated with the relation to the spin–spin coupling, this formulation is appropriate for *qualitative interpretations*. These methods will be used here to examine briefly some of the structural factors associated with geminal and vicinal H–H coupling constants.

4.1 Geminal Coupling Constants

Many features of geminal coupling can be rationalized by means of equations (46) and (63). Various terms in the numerator have opposite signs. Depending on the magnitudes of the various matrix elements, geminal H–H coupling constants could represent a delicate balance between terms of comparable magnitude but of opposite sign. The difficulty with early calculations of geminal coupling constants and the unusual sensitivity of geminal coupling constants to substituents and solvents would tend to support this view. Because of the renewed interest in the H–C–H angle dependence of $^2J(\text{H},\text{H}')$,^{144,145} it may be useful to reexamine the proposed dependence of 2J on the carbon hybridization. In equation (63) the most important term appears to be the geminal interaction integral $\beta_{cc'}$ since it is multiplied by 5. When expressed in terms of the diagonal matrix elements α_s and α_p in the s,p basis set, this term is proportional to the carbon s character a^2 ,

$$\beta_{cc'} = a^2(\alpha_s - \alpha_p) \quad (65)$$

If all of the integrals except this one could be neglected in the numerator of equation (63), the geminal coupling constants would be proportional to the products of the s character a^4 at the carbon atom. Therefore, the dependence of the coupling constants on the valence angle θ follows from the proportionality to a^4 and the relationship of a^2 to θ ,

$$a^2 = -\cos\theta/(1 - \cos\theta) \quad (66)$$

The slope of this function is $0.25 + 0.02$ between $\theta = 102$ and 129° .¹⁴⁴ Small variations of $\Delta\theta$ around both the tetrahedral and the trigonal interorbital angles should lead to approximately linear dependences of the geminal coupling constants on $\Delta\theta$. The recent ab initio MO data for $^2J(\text{H},\text{H}')$ of Geertsens et al.¹⁴⁵ indicate that this is the case. Their nonempirical results can also be fit to the expression

$$^2J(\text{H},\text{H}') = 160.6a_C^4 - 24.6 \text{ Hz} \quad (67)$$

which has a standard deviation of only 0.2 Hz.

4.2 Vicinal Coupling Constants

Because of their sensitivity to variations of dihedral angles, vicinal H–H nuclear spin–spin coupling constants ${}^3J(\text{H},\text{H}')$ have been used extensively for conformational studies. Much effort has been expended in specifying parameters for the torsion angle dependence for this type of coupling. Factors such as H–C–C internal angle dependence, C–C bond length dependence, and substituent electronegativity are also involved. Subsequent efforts have identified other factors, including substituent orientation and electronic contributions to ${}^3J(\text{H},\text{H}')$ from other groups in the molecule. Based on either the VB bond order formulation, MO sum-over-states perturbation, or group function formulations, there can be important contributions to the nuclear spin–spin coupling constants arising from groups that are outside the coupling path. An interesting example of this is the nonequivalence of the *exo–exo* and *endo–endo* vicinal coupling constants in bicyclo[2.2.1]heptanes.¹⁴⁶

4.2.1 Contributions from Remote Groups, e.g. Reasons for the Nonequivalence of Exo–Exo and Endo–Endo Coupling Constants

Attempts to refine the dihedral angle dependences of vicinal H–H coupling constants have demonstrated the importance of electronic factors outside the coupling path. An example of such an effect was the reason for the nonequivalence of the *exo–exo* and *endo–endo* coupling constants in the norbornane series.¹⁴⁶ In norbornanes it was observed that *exo–exo* coupling constants are several hertz larger than the *endo–endo* values even though both correspond to situations in which the dihedral angles are near 0°. These experimental trends were satisfactorily reproduced at the semiempirical (INDO-FPT) level. To investigate this nonequivalence a procedure was used in which certain nonbonded interactions between the ethanic bridge and other parts of the molecule were eliminated from the SCF procedure. Our first guess, that the most important interactions were between the two ethanic bridges of norbornane, turned out to be incorrect. Only on elimination of the interactions between the ethanic bridge and the methylene bridge did the two types of coupling become equivalent. These ideas have been incorporated into procedures for conformational analyses of 5-membered rings.^{147,148} It is not our intent to minimize the practical applicability of the many empirical equations, but this provides one example of the reason that there can be no universal equations to describe the conformation dependences of nuclear spin–spin coupling constants.

4.2.2 Dependence on H–C–C Internal Angles as well as Dihedral Angles

Substantial deviations of internal H–C–C angles from the tetrahedral values are common in strained, multicyclic compounds. Because of their relative rigidity, such compounds are most appropriate for unambiguously relating spin–spin coupling constants to molecular structures. There are some interesting examples which clearly show the importance of internal angle change, e.g. the monotonic decrease of H–C=C–H coupling with decreasing ring size in cycloalkenes. The 5.3 Hz ${}^3J(\text{H},\text{H}')$ in cubanes, which have C–C–H angles near 125°,

is just about one-half of the value expected in molecules with tetrahedral angles.

An explicit expression was derived¹⁴⁹ for vicinal H–H coupling constants ${}^3J_{(\text{H},\text{H}')}(\theta_1, \theta_2, \varphi)$ in terms of the two internal H–C–C angles θ_1 and θ_2 and the torsion angle φ . The resulting expression provides excellent correlations of most features of vicinal H–H coupling in ethanic (–CH–CH–), ethylenic (–CH=CH–), allylic (C=CH–CH–), and diene (C=CH–CH=C) moieties, and provide criteria for assessing the importance of internal angle changes. Because of the obvious extension of these equations to other spin–spin coupling situations, it is of interest to include a brief description of the results.

From equations (34) and (63) (and the proportionality of the matrix elements to overlap integrals in equation (64)) the vicinal coupling constants can be written in the form

$${}^3J_{(\text{H},\text{H}')}(\theta_1, \theta_2, \varphi) = c_a a(\theta_1, \theta_2) \cos^2 \varphi + \sum_i c_{bi} b_i(\theta_1, \theta_2) \cos \varphi + C \quad (68a)$$

where

$$a(\theta_1, \theta_2) = (1 + \cos \theta_1)(1 + \cos \theta_2) \quad (68b)$$

$$b_1(\theta_1, \theta_2) = \cot(\theta_1/2) \cot(\theta_2/2) \cos \theta_1 \cos \theta_2 \quad (68c)$$

$$b_2(\theta_1, \theta_2) = \cot(\theta_1/2) \cot(\theta_2/2) (\cos \theta_1 \cos \theta_2)^{1/2} \quad (68d)$$

$$b_3(\theta_1, \theta_2) = \cot(\theta_1/2) \cot(\theta_2/2) [\cos \theta_2 (-\cos \theta_1)^{1/2} + \cos \theta_1 (-\cos \theta_2)^{1/2}] \quad (68e)$$

The C term is usually small in magnitude when ${}^3J(\text{H},\text{H}')$ is written in the form of equation (35).¹⁴⁹ Equation (68) is an analytic expression but is subject to the many approximations that are implicit in the derivation.

In equations (68a)–(68e) the dependence of ${}^3J_{(\text{H},\text{H}')}$ on C–C internuclear separations occurs in the overlap integrals, which are implicit in the coefficients c_a , c_{bi} and C . Therefore, there will be a set of coefficients for each value of $r(\text{C}–\text{C})$. In the spirit of semiempirical MO methods, where the β integrals are determined empirically, these coefficients were based on a least squares analysis of the available experimental data. In deriving this equation from equation (64) it was assumed that the $\beta_{cc'}$ term is dominant and that other integrals will have the effect of slightly modifying the empirically determined coefficients.

The term containing $\cos^2 \varphi$ (the A term) in equation (68a) is the most important term controlling the vicinal coupling constants. The θ -dependence of the coefficient of this term [equation (68b)] is relatively simple when compared with the coefficients [equations (68c)–(68e)] of the $\cos \varphi$ term. Depicted in Figure 5 for ethanic coupling is a surface and contour plot of ${}^3J_{(\text{H},\text{H}')}(\theta_1, \theta_2, \varphi)$ on the internal angles $\theta_1 = \theta_2$ and the dihedral angle φ . The decrease in the magnitude of the vicinal coupling constants with increasing H–C–C angle is substantial, especially for the *trans* coupling. Clearly, the usual tendency to neglect the effects of internal angle changes

Figure 5 Surface and contour plots depicting the dependence of vicinal H–H coupling constants in an ethanic system as a function of the dihedral angle ϕ and the internal H–C–C angles $\theta_1=\theta_2$

cannot be justified in strained molecules or those with unusual bonding patterns.

1 INTRODUCTION

In general, J couplings (spin–spin couplings) are solvent dependent. This arises from subtle electronic changes which occur in the solute molecule as a result of intermolecular solute–solvent interactions. Therefore, a study of medium effects on J couplings is potentially able to provide intimate information on solute–solvent interactions.

Generally, there are a number of nonbonded and bonded solute–solvent interactions that may influence NMR parameters.¹ Clearly, the relative importance of these various interactions needs to be elucidated prior to any detailed investigation. The nonbonded interactions arise from electric field influences. These appear to operate by means of some type of electrostatic interaction between the solute and solvent molecules. Consequently, a model containing an account of the charge distribution in the interacting molecules would appear to be reasonable for the nonbonded interactions. A number of specific solute–solvent bonded interactions may also occur. Examples of these are weak molecular association, hydrogen bonding, ionic interactions and intramolecular change. From a knowledge of the chemistry of the solute and solvent concerned it is often possible to estimate the extent of any bonded interactions present. Such influences should be removed from consideration before turning to the effects of the nonbonded interactions.

A satisfactory model for quantitatively understanding solvent effects will inevitably include a realistic description of the charge distribution of the solute molecule. However, the solvent molecules need not be treated so specifically. The simplest approach is to consider the solvent as a continuum surrounding the solute molecule. Several different models of this type have been proposed to understand nonbonded solute–solvent effects on J coupling. Inevitably, the polarity of the solvent medium enters into their formulation. The main purpose of this section is to provide a substantial elucidation of the nature of solute–solvent interactions in J coupling through theoretical and experimental estimates of J coupling.

2 THE EFFECT OF NONBONDED INTERACTIONS ON J COUPLINGS

The three major contributions to J coupling arise from the contact, orbital, and dipolar interactions.² The J coupling involving hydrogen nuclei is predominantly governed by only the contact interaction. However, the J coupling between non-hydrogen nuclei is governed by all three interactions. Within the self-consistent perturbation framework these contributions to $J(A,B)$, the spin–spin coupling interaction between nuclei A and B, are given by equations (1)–(3).

The contact contribution, J_c , can be defined as

$$J_c(A,B) = (32/9)h\pi\mu_0\mu_B^2\gamma_A\gamma_B S_A^2(0)S_B^2(0)P_{S_B S_B}^\alpha \quad (1)$$

where μ_0 is the permeability of a vacuum, μ_B is the Bohr magneton, $[\gamma]$ is the nuclear magnetogyric ratio divided by 2π , $S^2(0)$ is the s electron density at the nucleus concerned and $P_{S_B S_B}^\alpha$ refers to a diagonal element of the charge density, bond order matrix for s electron spin orbitals on nucleus B with α spin.

The orbital term, J_O , is given by

$$J_O(A,B) = (2\mu_0\mu_B^2 h\gamma_A\gamma_B/3\pi)\langle r_A^{-3} \rangle_p \langle r_B^{-3} \rangle_p \times (P_{x_B y_B} + P_{z_B y_B} + P_{x_B z_B}) \quad (2)$$

where $\langle r^{-3} \rangle_p$ refers to the expectation value of the inverse cube of the separation between the nucleus concerned and its p electrons and $P_{x_B y_B}$ is the charge density, bond order matrix element for the p_x and p_y orbitals on atom B.

Finally, the dipolar expression, J_D , is

$$J_D(A,B) = (\mu_0\mu_B^2 h^3\gamma_A\gamma_B/20\pi^3)\langle r_A^{-3} \rangle_p \langle r_B^{-3} \rangle_p \times (2P_{z_B z_B}^{\alpha\alpha} - P_{x_B x_B}^{\alpha\alpha} - P_{y_B y_B}^{\alpha\alpha} + 3P_{x_B z_B}^{\alpha\beta} - 3Q_{y_B y_B}^{\alpha\beta}) \quad (3)$$

where Q refers to the imaginary part of the charge density, bond order matrix.

As shown by equations (2) and (3), the orbital and dipolar contributions arise for nuclei with p valence electrons whereas equation (1) reveals that the presence of s electrons is necessary for the contact interaction.

In the absence of specific association effects the solvent dependence of coupling interactions is related to the polarity of the medium. This dependence has been studied theoretically by means of the reaction field model, a cubic closest packed cluster model and solvation model (see Section 2.2 below).

2.1 Reaction-Field Type Solvent Effect

This provides the simplest theoretical description of the interactions occurring between polar solute and polar solvent molecules.^{3–5} The model treats the solute as a polarizable point dipole centered in a spherical cavity within the dielectric continuum formed by the solvent molecules. It is assumed that the solute point dipole polarizes the surrounding medium, thus creating a reaction field which is parallel to its dipole moment. By taking the direction of the dipole moment vector,

μ , to be from the positive to negative charge on the solute, the reaction field, R , lies in the same direction as μ . The relationship between R and μ is given by equation (4).

$$R = 2\mu(\epsilon - 1)(n^2 - 1)/3\alpha(2\epsilon + n^2) \quad (4)$$

where n is the refractive index of the solute, α is its polarizability, μ refers to the solute point dipole and ϵ is the dielectric constant of the solvent. Linear relationships have been reported between J coupling interactions and the reaction field parameter.

Since ^1H and ^{19}F nuclei are often on the surface of the solute molecule they are more directly exposed to solvent molecules than are skeletal nuclei such as ^{13}C , ^{15}N or ^{31}P . Consequently, equation (4) may need to be modified to include local effects due to polar groupings on neighboring solvent molecules when considering J couplings between peripheral nuclei.

In calculations of the effects of the reaction field on J couplings both magnetic and electric reaction fields have been considered. The inclusion of reasonable numbers in the expression obtained in the magnetic field case results in solvent effects of about 1 Hz, which is much smaller than those observed for a number of J couplings. Thus, only electrostatic interactions between the solute and solvent molecules have been extensively considered in the reaction field. A simplified sum-over-states perturbation theory was applied to the study of the electrostatic interaction. In this approach the contact contribution to the J coupling is given by⁶

$$J_c(\text{A,B}) = \pi h \mu_0 \mu_B^2 \gamma_A \gamma_B S_A^2(0) S_B^2(0) \pi_{AB} \quad (5)$$

where the mutual atom-atom polarizability, π_{AB} , is expressed as

$$\pi_{AB} = 4 \sum_j^{\text{occ}} \sum_k^{\text{unocc}} (\epsilon_j - \epsilon_k)^{-1} C_{j,S_A} C_{k,S_A} C_{j,S_B} C_{k,S_B} \quad (6)$$

where ϵ_j and ϵ_k refer to the energies of the j occupied and k unoccupied molecular orbitals, respectively, and the C terms are the coefficients for the s orbitals on atoms A and B in these molecular orbitals. The value of π_{AB} is related to the empirical resonance and Coulomb integrals. The electric field dependence of π_{AB} is introduced by means of these empirical parameters to obtain an estimate of the solvent dependence of $J_c(\text{A,B})$. However, the formulation employed for the electric field effects on these parameters has been criticized. Additionally, it is claimed that the reported results are fortuitous since the transfer of electron density out of the C-H bonding region is not considered. The inclusion of this electron transfer produces satisfactory agreement between the calculated and observed solvent effects on $^2J(\text{H,H})$ when Intermediate Neglect of Differential Overlap (INDO) parameters are employed.

More comprehensive calculations of J couplings, within the reaction field framework, have included a term describing the interaction between the solute molecule and neighboring electrostatic fields in the Hamiltonian governing the J coupling interaction. The solvent effects on the J couplings, $\Delta J(\text{A,B})$, are calculated from⁷

$$\Delta J(\text{A,B}) = 10^{-5}(|R| - |R_0|)[\Delta J(\text{A,B})_E] \quad (7)$$

where $|R|$ and $|R_0|$ are the magnitudes of the reaction field, given by equation (4), in the solvent of interest and in cyclohexane, respectively. $\Delta J(\text{A,B})$ is the difference in the J coupling constant calculated for the isolated molecule, $\epsilon = 1$, and that due to the addition of an electric field of 10^5 esu cm^{-2} . The use of equation (8) is apparently justified by the linearity of changes in the calculated J coupling constants as a function of the reaction field for values of the latter as large as 3×10^5 esu cm^{-2} . The calculation explains well the experimental data.

2.2 Solvation Type Solvent Effect

Some attempts to perform direct quantum chemical calculations on a solvated molecule have been reported.⁸ Treatments of solvent effects on nuclear shielding^{9,10} and the J coupling constant¹¹⁻¹⁴ by means of the solvation theory in conjunction with MO methods have been published. This procedure has been used to compute the wavefunctions of molecules under the influence of the solvent considered as a perturbation.

According to the solvation model, it is assumed that the solvent molecule induces a number of charges, the solvatons, in a solvent of dielectric constant ϵ : one solvation is associated with each atom of the solute, and its charge is equal in magnitude but opposite in sign to the net charge of the atom to which it is attached. There are no interactions between the solvatons. On the basis of this model, the Hamiltonian, $\hat{\mathcal{H}}$, of a particular molecule with M electrons and N nuclei consists of the inherent term, $\hat{\mathcal{H}}_{\text{inh}}$, and the solute-solvent interaction term, $\hat{\mathcal{H}}_{\text{solv}}$, and is given, in atomic units, by equations (8)-(10).⁹

$$\hat{\mathcal{H}} = \hat{\mathcal{H}}_{\text{inh}} + \hat{\mathcal{H}}_{\text{solv}} \quad (8)$$

$$\begin{aligned} \hat{\mathcal{H}}_{\text{inh}} = & \sum_{i=1}^M \left(-\nabla_i^2 - \sum_{n=1}^N \frac{Z_n}{r_{ni}} \right) + \frac{1}{2} \sum_i^M \sum_j^M \frac{1}{r_{ij}} \\ & + \frac{1}{2} \sum_k^N \sum_l^N \frac{Z_k Z_l}{r_{kl}} \end{aligned} \quad (9)$$

$$\hat{\mathcal{H}}_{\text{solv}} = \frac{\epsilon - 1}{2\epsilon} \left(\sum_i^M \sum_s^N \frac{Q_s}{r_{si}} - \sum_r^M \sum_k^N \frac{Q_s Z_k}{r_{sk}} \right) \quad (10)$$

where Q_s is the induced solvation charge, r_{si} and r_{sk} are the solvation-electron and solvation-nucleus separations, respectively, and Z is the nuclear charge. The Born equation is used to approximate the solvent-solute interactions. If the atomic orbitals (AOs) and solvation are associated with the same center, the solvation-electron distance, r_{si} , is approximated by the van der Waals radius of the particular type of atom. If the AOs and solvation are associated with different atomic centers, the solvation is assumed to be centered on the atom associated with it and then r_{si} is evaluated accordingly.

This model has been employed within the Finite Perturbation Theory (FPT) formalism, in an attempt to understand the effects of solvents on $^1J(\text{C,H})$, $^3J(\text{H,H})$ and $^3J(\text{C,H})$ couplings. The approach adopted considered only the contact interaction and the spin-unrestricted self-consistent field

equations of the Fock matrices, $F_{\mu\nu}^\alpha$ and $F_{\mu\nu}^\beta$, for α and β electron spins become¹⁰

$$F_{\mu\nu}^\alpha = H_{\mu\nu}^{\text{core}} + \sum_{\lambda\sigma} [P_{\lambda\sigma}(\mu\nu | \lambda\sigma) - P_{\lambda\sigma}^\alpha(\mu\sigma | \lambda\nu)] + \frac{\epsilon - 1}{\epsilon} \times \int \phi_\mu \left(\sum_s^N \frac{Q_s^\alpha}{r_{sl}} \right) \phi_\nu d\tau + \frac{8}{3}\pi\beta_\mu \int \phi_\mu \delta(r_B) \phi_\nu dr \quad (11)$$

$$F_{\mu\nu}^\beta = H_{\mu\nu}^{\text{core}} + \sum_{\lambda\sigma} [P_{\lambda\sigma}(\mu\nu | \lambda\sigma) - P_{\lambda\sigma}^\beta(\mu\sigma | \lambda\nu)] - \frac{\epsilon - 1}{\epsilon} \times \int \phi_\mu \left(\sum_s^N \frac{Q_s^\beta}{r_{sl}} \right) \phi_\nu d\tau - \frac{8}{3}\pi\beta_\mu \int \phi_\mu \delta(r_B) \phi_\nu dr \quad (12)$$

where the fourth terms in equations (11) and (12) represent the contact interaction and $\delta(r_B)$ is the Dirac delta function which describes the contact between electrons and nucleus B; the other symbols have their usual meaning. The charges Q_s^α and Q_s^β for the α and β spins, respectively, on the solvaton are assumed to be equal in magnitude but opposite in sign to those on the atom to which it is attached. The J coupling is calculated by means of the FPT method incorporating the Fock matrices given by equations (11) and (12).

The effects of solvents on the directly bonded ^{13}C -H couplings of acrylonitrile, dichloromethane, chloroform, difluoromethane and trifluoromethane have been estimated by this procedure. The tendency for the calculated values to increase with increasing ϵ agrees qualitatively with the observed tendency, except in the case of $^1J(\text{C-1,H-B}) + ^1J(\text{C-1,H-C})$ for acrylonitrile.^{11,12}

The values of $^1J(\text{C,H})$ produced by the solvaton model can be fit approximately by equation (13).

$$^1J(\text{C,H}) = a(\epsilon - 1)/\epsilon + b((\epsilon - 1)/\epsilon)^2 + c \quad (13)$$

The observed values of $^1J(\text{C,H})$ fall approximately on a straight line when plotted against $(\epsilon - 1)/\epsilon$. Consequently the second term in equation (13) can be neglected. By plotting $^1J(\text{C,H})$ against $(\epsilon - 1)/\epsilon$, the values of a and c are obtained: in acetonitrile the $^1J(\text{C-2,H-A})$ data give $a = 3.9 \text{ Hz}$ and $c = 176.1 \text{ Hz}$; in dichloromethane $a = 28.0 \text{ Hz}$ and $c = 153.0 \text{ Hz}$; in chloroform $a = 36.0 \text{ Hz}$ and $c = 182.0 \text{ Hz}$; in difluoromethane $a = 7.7 \text{ Hz}$ and $c = 178.0 \text{ Hz}$; in trifluoromethane $a = 22.5 \text{ Hz}$ and $c = 225.0 \text{ Hz}$.^{11,12} By comparing various substituted methanes the values of a are found to be larger for chlorine-substituted than fluorine-substituted molecules, and those for trisubstituted methanes are larger than for disubstituted methanes. The magnitude of a provides a measure of the solvent effect on $^1J(\text{C,H})$; thus an increase in the number of halogen-substituted atoms in methane leads to an increase in the solvent effect. In general, it seems that the solvaton model is able to reproduce the gross experimental trends of the effects of solvation on the J couplings considered.

2.3 Solvent Effects on the J Couplings of Flexible Molecules

The molecules mentioned above are considered to be rigid. However, there is another category of solvent effects of J couplings, namely, those on the coupling constants of molecules that can adopt two or more conformations. For these molecules, the observed J coupling $\langle J \rangle_{\text{obs}}$ is given by

$$\langle J \rangle_{\text{obs}} = \sum_i X_i J_i \quad (14)$$

where X_i and J_i are the molar fraction and J coupling, respectively, of conformer i . It is shown that the solvent-induced changes of $^1J(\text{C,H})$ are very large when compared with temperature-induced changes and the greater change is proof of the larger contribution of the solvent-induced electronic changes in the solute molecules to the solvent effects of $^1J(\text{C,H})$ than of the contribution arising from changes in the relative populations of the conformers.

Since Karplus's prediction of a strong conformational dependence of vicinal proton-proton J couplings of ethane derivatives, peptide systems and various other molecules have received the attention of many investigators. They have considered the dihedral angle, ϕ , dependence of vicinal J couplings in an isolated molecule in a similar manner to that given by the Karplus relationship.¹⁵

$$^3J(\text{H,H}) = A + B \cos \phi + C \cos 2\phi \quad (15)$$

where A , B and C are coefficients to be determined for the system under consideration. In order to provide a more exact insight into the relationship between the magnitude of the vicinal coupling and the conformation, solvent effects must be taken into account. Ando and co-workers have provided a theoretical prediction of solvent effects on vicinal proton-proton and proton-carbon J couplings.^{12,16-18}

The values of the coefficients A , B and C for ethane, $\text{CHCl}_2\text{CHCl}_2$ and *trans*- N -methylformamide, have been calculated as a function of ϵ by means of the FPT-INDO and FPT-Complete Neglect of Differential Overlap/2 approximations within the solvaton model.¹² For the H-C-N-H J couplings the values of the coefficients are smaller than those appropriate to the H-C-C-H and H-C-N-H couplings. The value of B in the former is somewhat larger than in the latter case. The calculated absolute values of the coefficients A , B and C show an increase with increasing ϵ except for the case of the coefficient C for $^3J(\text{C,H})$ in *trans*- N -methylformamide obtained from INDO calculations. The values of A , B and C show the following dependence on ϵ :

$$A, B \text{ or } C = a'(\epsilon - 1)/\epsilon + b' \quad (16)$$

where a' is a measure of the strength of the dielectric solvent effect on the A , B and C coefficients and b' is the value of A , B or C at $\epsilon = 1$. From these results, the calculated solvent dependence may be represented by

$$J = b(\epsilon - 1)/\epsilon + c \quad (17)$$

where b is a measure of the strength of the dielectric solvent effect on the vicinal J coupling constants, and c represents the

J coupling values of the *trans* and *gauche* conformers for an isolated molecule (at $\epsilon = 1$).

An oriented clustering of the polar solvent molecules around the polar solute molecule is assumed for solvent effects of J couplings.¹⁹ The solute molecule has its dipole moment parallel to the z axis and the directions of the solvent dipoles are as indicated. Such a model may be reasonably expected to be more satisfactory than the simple reaction field model for peripheral solute nuclei which are more exposed to the influences of individual solvent molecules. In this approach the solvent and solute molecules are recognized as belonging to distinct groups with the assumption of strong orthogonality between them. The interactions between these groups are described by including attraction terms between the electrons of the solute and the nuclei of the solvents as well as intermolecular Coulomb repulsion integrals in the Hamiltonian accounting for the spin–spin interaction. In comparison with the reaction field results, it is noteworthy that those presented for formaldehyde show the correct sign and magnitude for the solvent effect on $^2J(\text{H,H})$ in acetonitrile as solvent.

3 EFFECT OF PRESSURE ON J COUPLINGS

The application of pressure to pure liquids and solutions leads to a decrease of intermolecular distance.²⁰ Such an intermolecular change is reflected in a variation of the electronic distribution within a given molecule. This will, inevitably, be revealed by changes in the J coupling.

The pressure dependence of the directly bonded ^{13}C –H couplings for the methyl groups of ^{13}C -enriched acetaldehyde and methanol have been reported.^{21,22} The value of $^1J(\text{C,H})$ is found to increase linearly with increasing pressure. The experimental data have been clarified by the solvaton theory. As mentioned above, an increase in pressure usually results in a decrease in intermolecular distance and in an increase in the value of the dielectric constant for acetaldehyde and methanol. Thus, the pressure dependence of $^1J(\text{C,H})$ contains the pressure effect on the intermolecular distance and on the dielectric constant. The solvaton–nucleus distance r_{sk} in equation (10) corresponds to the intermolecular distance. In the calculation, it is assumed that a variation in r_{sk} mimics the effect of changing the external pressure of the experimental system. Calculations containing such an interaction show that the pressure dependence of the J coupling arises predominantly from a change in the intermolecular distances, and is not due to the simultaneous change in the dielectric constant.

1 INTRODUCTION

In many fields, semiempirical calculations have been replaced by more reliable ab initio calculations, but this is not the case for the calculations of J coupling constants in organic molecules of chemical interest. The presence of triplet instabilities, a common feature for ab initio wavefunctions, requires higher levels of perturbation theory to obtain even approximate results when using ab initio methods to calculate J couplings, making ab initio methods almost inapplicable to calculating J couplings in large molecules. Therefore, the discussion of the semiempirical methods commonly used to calculate J couplings has not only an historical value but also provides important practical information on how to calculate and to analyze J couplings.

The calculation of spin–spin J couplings has been discussed in four comprehensive reviews on the subject during the last 20 years^{1–4} where the interested reader can find in great detail the advances achieved in this field. The theoretical formulation of the coupling constants is also discussed in Barfield’s article in this Encyclopedia (see *Indirect Coupling: Theory and Applications in Organic Chemistry*).

2 EARLY SEMIEMPIRICAL METHODS

Early attempts to calculate J couplings using molecular quantum mechanical methods were characterized by the use of the so called ΔE approximation. This approximation involves the use of ad hoc empirical or semiempirical parameters instead of the direct evaluation of the Ramsey formulae⁵ using perturbation theory. The limited space of this article precludes a detailed derivation of the relevant expressions for the coupling constants under these approximations, but it is sufficient to say that using the ΔE and the LCAO (Linear Combination of Atomic Orbitals) approximations for the molecular wavefunction we can write the contributions to the J couplings from the different interaction mechanisms as:

Fermi Contact (FC) term

$$K_{\text{NN}'}^{(3)} = \frac{64\pi^2\beta^2}{9}({}^3\Delta E)^{-1}P_{\text{NN}'}^2\phi_{\text{N}}^2(0)\phi_{\text{N}'}^2(0) \quad (1)$$

Paramagnetic Spin Orbital (PSO) term

$$K_{\text{NN}'}^{(1)} = \frac{8\beta^2}{3}({}^1\Delta E)^{-1}\langle r_{\text{N}}^{-3} \rangle \langle r_{\text{N}'}^{-3} \rangle (P_{x_{\text{N}}x_{\text{N}'}}P_{y_{\text{N}}y_{\text{N}'}} + P_{y_{\text{N}}y_{\text{N}'}}P_{z_{\text{N}}z_{\text{N}'}} + P_{z_{\text{N}}z_{\text{N}'}}P_{x_{\text{N}}x_{\text{N}'}} - P_{x_{\text{N}}y_{\text{N}'}}P_{y_{\text{N}}x_{\text{N}'}} - P_{y_{\text{N}}z_{\text{N}'}}P_{z_{\text{N}}y_{\text{N}'}} - P_{z_{\text{N}}x_{\text{N}'}}P_{x_{\text{N}}z_{\text{N}'}}) \quad (2)$$

Spin Dipolar (SD) term

$$K_{\text{NN}'}^{(1)} = \frac{4\beta^2}{25}({}^3\Delta E)^{-1}\langle r_{\text{N}}^{-3} \rangle \langle r_{\text{N}'}^{-3} \rangle \times [2(P_{x_{\text{N}}x_{\text{N}'}}^2 + P_{y_{\text{N}}y_{\text{N}'}}^2 + P_{z_{\text{N}}z_{\text{N}'}}^2) + 3(P_{x_{\text{N}}x_{\text{N}'}}P_{y_{\text{N}}y_{\text{N}'}} + P_{y_{\text{N}}y_{\text{N}'}}P_{z_{\text{N}}z_{\text{N}'}} + P_{z_{\text{N}}z_{\text{N}'}}P_{x_{\text{N}}x_{\text{N}'}}) - (P_{x_{\text{N}}y_{\text{N}'}}^2 + P_{y_{\text{N}}x_{\text{N}'}}^2 + P_{y_{\text{N}}z_{\text{N}'}}^2 + P_{z_{\text{N}}y_{\text{N}'}}^2 + P_{z_{\text{N}}x_{\text{N}'}}^2 + P_{x_{\text{N}}z_{\text{N}'}}^2) + 3(P_{x_{\text{N}}y_{\text{N}'}}P_{y_{\text{N}}x_{\text{N}'}} + P_{y_{\text{N}}z_{\text{N}'}}P_{z_{\text{N}}y_{\text{N}'}} + P_{z_{\text{N}}x_{\text{N}'}}P_{x_{\text{N}}z_{\text{N}'}})] \quad (3)$$

where we have used standard quantum chemical notation for the quantities describing the wavefunction and assumed that the LCAO expansion contains only 1s, 2s and 2p orbitals. ΔE is an empirical parameter which represents the average excitation energy between the ground state and the excited electronic states (triplets for the FC and SD terms and singlets for the PSO term). In many cases this parameter has been correlated with the UV spectrum of the molecules under consideration. $\langle r^{-3} \rangle$ is an empirical parameter which represents the average of the cube of the distance between the electrons and the nucleus; this parameter takes into consideration the contraction and expansion of the atomic orbitals due to different bonding strengths. Finally, $\phi_{\text{N}}^2(0)$ is the electron density at the position of the nucleus and $\mathbf{P}$ is the electronic density matrix.

Equations (1)–(3) provide a very simple way to calculate and to analyze some of the most relevant features of the coupling constants, but also predict some disturbing properties. Perhaps the most serious drawback of equations (1)–(3) is that they predict zero paramagnetic spin orbital and dipolar contributions for any coupling constant involving protons. Note that because protons do not have p orbitals, equations (2) and (3) are exactly zero when one of the nuclei is a proton. This has been a common assumption in many semiempirical calculations of coupling constants that is not supported either by more elaborate semiempirical calculations or by ab initio results. Nevertheless, equations (1)–(3) are usually successful in predicting qualitative trends in molecules belonging to the same family. In many cases the deficiencies and/or systematic errors of the calculations can be taken into account by adjusting the empirical parameters, ΔE , $\phi_{\text{N}}^2(0)$ and $\langle r^{-3} \rangle$ to reproduce the experimental values of the coupling constants in a selected set of coupling constants.

The early semiempirical formulations totally ignored the diamagnetic spin orbital (DSO) term, which until recent years was considered negligible.⁶ Recent calculations using ab initio as well as semiempirical methods have shown that this assumption is incorrect for many kinds of coupling constants.⁴

3 FINITE PERTURBATION THEORY

The most significant advance in the semiempirical calculation of J coupling constants has been the introduction of the INDO-FPT (Intermediate Neglect of Differential Overlap-Finite Perturbation Theory) method by Pople and co-workers in 1968.⁷ The success of this method has been extensively documented and it is still today the most popular method for semiempirical calculations of coupling constants. The original formulation of the method calculated only the FC interaction but later, using the equivalent CHF (Coupled Hartree-Fock) perturbation scheme, was extended by Blizzard and Santry to include all the second order noncontact interactions.⁸

The original idea behind Pople's work was to realize that the coupling constants or their reduced couplings can be expressed as the second derivative of the total energy of the molecule with respect to the magnetic moments, μ_N and $\mu_{N'}$, of the coupled nuclei:

$$K_{NN'} = \left[\frac{\partial^2 E(\mu_N, \mu_{N'})}{\partial \mu_N \partial \mu_{N'}} \right]_{\mu_N = \mu_{N'} = 0} \quad (4)$$

For the FC term this derivative can be transformed using the Hellmann-Feynman theorem and the INDO approximation into a compact expression in terms of the derivative of the spin density at the position of the nucleus N with respect to the magnetic moment of the nucleus N' . The final expression for the FPT-INDO calculations of the FC term is:

$$K_{NN'}^{(3)} = \left(\frac{8\pi\beta}{3} \right)^2 s_N^2(0) s_{N'}^2(0) \frac{\rho_{s_N s_N}(h_{N'})}{h_{N'}} \quad (5)$$

where $s_N(0)$ is the electronic density at the position of the nucleus N and the derivative of the spin density has been calculated by its finite difference quotient. $\rho_{s_N s_N}(h_{N'})$ is the spin density at the nucleus N when a magnetic moment of intensity $h_{N'}$ is placed at the position of the nucleus N' . The spin density can be estimated, in an open shell calculation, as the difference between the electronic density of the electrons with α and β spins. This formulation of the FPT-INDO theory is straightforward to implement, requiring only minor modifications of any standard program for molecular orbital (MO) calculations. Unfortunately the FPT method is computationally very inefficient, requiring a large number of self-consistent field calculations when all of the noncontact interactions are considered. In recent years the FPT-INDO and the CHF-INDO methods of calculating coupling constants have been reformulated in terms of the computationally more efficient Polarization Propagator Approach. A comprehensive program to perform semiempirical calculations of coupling constants including all the interactions as well as certain capabilities to analyze their transmission mechanisms is available from the Daresbury Library of computer programs.⁹

In Figure 1 we present the correlation between calculated and experimental J couplings for selected $J(\text{C,H})$, $J(\text{C,C})$ and $J(\text{H,H})$ in a variety of compounds. Results for J values involving other nuclei are in general satisfactory, but serious difficulties have been found for couplings involving fluorine and other electronegative atoms. Unfortunately, there is no systematic way to improve the quality of the semiempirical methods and therefore it is necessary to test the validity of the method for each type of coupling constant.

Figure 1 Comparison of the experimental and calculated values of selected J coupling constants. The calculations were done using the CHF (Coupled Hartree-Fock) method with the INDO parameterization. (a) $J(\text{C,H})$, $R^2 = 0.8099$; (b) $J(\text{C,C})$, $R^2 = 0.9576$; (c) $J(\text{H,H})$, $R^2 = 0.9248$. All the values are in Hz; the calculations of the $J(\text{C,H})$ and $J(\text{H,H})$ include only the Fermi contact term while the calculations for $J(\text{C,C})$ include all the second order terms

Over the years many attempts have been made to improve the results obtained using the original INDO parameterization, but most of them have been either unsuccessful or produced marginally better results. The Modified Neglect of Differential Overlap (MNDO) method of Dewar and Thiel,¹⁰ which has become the most common method for the semiempirical calculation of molecular properties, has not been successful in the calculations of J couplings because the MNDO wavefunctions in unsaturated compounds exhibit triplet instabilities which preclude CHF calculations of J couplings. The origin of the triplet instabilities has been traced to the large difference between the β^0 parameters used in the MNDO method for the s and p orbitals.¹¹

The INDO based semiempirical methods were originally formulated to calculate coupling constants involving first row atoms (H–F), but a number of extensions have been reported and now this method is commonly used for calculations of couplings between nuclei in the first two rows of the Periodic Table. Calculations including heavier atoms can also be found in the literature but they are less common and their results are less reliable.

Extensive calculations of coupling constants involving heavy atoms have been performed using the REX (Relativistic Extended Hückel Theory) and the ITREX (Iterative Relativistic Hückel Theory) methods.¹² A computer program, REXNMR,¹³ is available from the Quantum Chemistry Program Exchange to perform this kind of calculation in molecules including any element of the Periodic Table. The results achievable with these methods are dependent on the type of coupling constant considered, but in general the comparison of the results obtained with the EHT (Extended Hückel Theory) without relativistic corrections and those with the corrections shows that the relativistic corrections are quite important when one of the coupled nuclei belongs to the third row or higher. Some examples of this behavior are depicted in Figure 2.

4 TRANSMISSION MECHANISMS OF THE COUPLING CONSTANTS

The understanding of the transmission mechanisms of the coupling constants is important in gaining information on the intimate relationship between the electronic structure of molecules and the coupling constants. The semiempirical MO formulations, like the FPT-INDO method discussed above, cannot provide a direct interpretation of the origin of the couplings as in equations (1)–(3), but in recent years a great deal of effort has been dedicated to the development of methods to provide a better understanding of the transmission mechanisms of the coupling constants.

While the methods of studying transmission mechanisms are independent of the kind of wavefunction used in the calculation of the coupling constants, most of the applications of these methods have used semiempirical approximations of the wavefunctions.¹⁴ The early work in this field was based on the PRMO (Partially Restricted Molecular Orbitals)¹⁵ and the NNBI (Neglect of Non Bonded Interactions)¹⁶ methods, which use the FPT-INDO formulation to calculate coupling constants. Both methods are based on the selective exclusion from the calculations of certain transmission paths by either

Figure 2 Reduced coupling constants between directly bonded atoms, $^1K(\text{H},\text{X})$, in simple hydrides. The uppermost value is the calculated REX value, the number in parentheses is the nonrelativistic EHT value (when different from the relativistic one). The lowest value is the experimental coupling. The calculated results are from Pyykkö and Wiesenfeld.¹³ All the values are in $10^{19} \text{ m}^{-2} \text{ kg s}^{-2} \text{ Å}^{-2}$. (Reproduced by permission of Academic Press from J. Kowalewski.³)

the equalization of the spin populations along the paths (PRMO) or neglecting electronic interactions between the electrons localized along the paths and the rest of the molecule (NNBI). The first applications of these methods were concentrated on the study of the separation of the electronic σ – π components¹⁵ and the through-space or nonbonded contributions¹⁶ to the coupling constants. These approaches to analyzing the transmission mechanisms were very successful in reproducing well established empirical rules like the methyl replacement rule, the sign alternation of the π electron transmitted contributions, the dominance of π electron transmitted contributions in long-range couplings, the W rule for the σ transmitted contributions, etc. As an example, in Table 1 we present PRMO results that show how the methyl substituent rule is verified in toluene.

The success of these methods prompted the extension of the PRMO ideas to the more general formulation of the CLOPPA (Contributions from Localized Orbitals within the Polarization Propagator Approach) method.¹⁷ This approach allows the expression of any coupling constant as a sum-over-contributions arising from arbitrarily defined molecular fragments. The CLOPPA method has been formulated for all of the interaction mechanisms. It is self evident that the first order DSO contribution can be written as a sum-over-molecular fragments. This is done by summing the average value of the interaction Hamiltonian over the projection of the wavefunction onto the localized orbitals representing the different fragments:

$$J_{\text{NN}'}^{\text{DSO}} = \sum_{i=\text{occ}} \langle i | \hat{\mathcal{H}}(1, 1) | i \rangle \quad (6)$$

where $|i\rangle$ is an occupied localized MO and $\hat{\mathcal{H}}(1, 1)$ is the Hamiltonian for the DSO contribution. The decomposition of the second-order contributions presents more complicated

Table 1 Comparison of the Experimental Benzylic Couplings in Toluene with their PRMO Calculated π -Transmitted Components and the π -Transmitted Components of the Respective $n-1J(\text{H,H})$ Couplings in Benzene. All Values in Hz. (Values from A. R. Engelmann et al.¹⁵)

Coupling	Experimental	Full INDO	π -transmitted components	
			$nJ(\text{H,H})$ in toluene	$n-1J(\text{H,H})$ in benzene
$^4J(\text{H}, \text{CH}_3)$	-0.75	-0.92	-0.67	0.60
$^5J(\text{H}, \text{CH}_3)$	0.36	0.69	0.41	-0.43
$^6J(\text{H}, \text{CH}_3)$	-0.62	-0.64	-0.57	0.51

expressions which involve the use of the polarization propagator inner projected onto the localized orbitals defining the molecular fragments. This is:

$$J_{\text{NN}'}^2 = \sum_{ia,jb} U_{ia,N} W_{ia,jb} U_{jb,N'} \quad (7)$$

where the sum runs over all possible transitions between localized occupied (i,j) and unoccupied (a,b) molecular orbitals. W is the inner projector of the singlet (PSO term) or triplet (FC and SD terms) polarization propagator. The U operators are the perturbators given by:

$$U_{ia,N}^{\text{FC}} = \langle i | \delta(\mathbf{r}_N) | a \rangle \quad (8)$$

$$U_{ia,N}^{\text{PSO}} = -i \left\langle i \left| \frac{\hat{\mathbf{L}}_N}{r_N^3} \right| a \right\rangle \quad (9)$$

$$U_{ia,N}^{\text{SD},\alpha\beta} = \left\langle i \left| \frac{3r_{N\alpha}r_{N\beta} - r_N^2\delta_{\alpha\beta}}{r_N^5} \right| a \right\rangle \quad (10)$$

for the FC, PSO and SD terms, respectively. If all the MOs are included in equations (6) and (7) then the equations give expressions for the total couplings; a partial sum over the localized MOs belonging to a particular molecular fragment provides an estimate of the contribution to the coupling constant from that particular fragment. The CLOPPA analysis is a powerful tool for understanding the mechanisms of transmission of the coupling constants and in principle can be implemented for any approximation of the molecular wavefunction. In analyzing the results of this method it is always important to remember that the partition of the molecule into fragments is arbitrary and that the projections of wavefunctions onto the different molecular fragments do not always form an orthogonal set. Therefore the additivity of the contributions from different molecular fragments does not hold exactly.

The CLOPPA partition of the spin coupling constants has been used mostly with the INDO approximation of the molecular wavefunction because of the great success of the INDO parameterization in calculating the spin-spin coupling constants. Note that when using the first order approximation for the propagator and the INDO parameterization for the Hamiltonian, equations (6) and (7) are exactly equivalent to the FPT or CHF methods discussed above if all the occupied and vacant orbitals are included in the calculation.

5 CONCLUSIONS

Semiempirical calculations using the INDO parameterization are still the state of the art for calculating coupling constants in organic molecules with more than a handful of atoms. The lack of systematic ways of improving semiempirical calculations has been a significant hurdle in this field and we do not expect that it will be overcome soon. Progress in ab initio methods has been slow and its applicability to medium and large organic molecules has to wait for the development of efficient computer programs to calculate J couplings including correlation effects. In the meantime judicious semiempirical calculations and analysis of the transmission mechanisms of the J coupling constants can be used as tools for electronic structure determination.

1 INTRODUCTION

Nuclear spins can interact with one another by two fundamentally different mechanisms: (1) a direct-dipolar interaction and (2) an indirect nuclear spin–nuclear spin coupling involving the intervening electrons in a molecule (see **Dipolar & Indirect Coupling Tensors in Solids**, Volume 3). The latter interaction may be thought of as a two-stage process whereby the spin of one nucleus, *N*, polarizes a nearby electron spin and the resulting infinitesimally small spin polarization is transferred to other electrons which in turn transfer their polarization to a second nucleus, *N'*. On the other hand, the direct dipolar interaction between two nuclei does not involve the electronic framework of the molecule. The classical analogue is the direct through-space interaction between two magnetic point dipoles, μ_N and $\mu_{N'}$, which is known to depend on the value of $\langle r_{NN'}^{-3} \rangle$ where *r* is the internuclear separation. The interaction energy of a pair of isolated nuclear spins *N* and *N'* may be represented by

$$E_{NN'} = h\mathbf{I}_N \cdot (\mathbf{D} + \mathbf{J}) \cdot \mathbf{I}_{N'} \quad (1)$$

where *h* is Planck's constant, $\mathbf{I}_N$ and $\mathbf{I}_{N'}$ represent the nuclear spin angular momentum vectors associated with nuclei *N* and *N'*, respectively, **D** is the direct dipolar spin–spin coupling tensor and **J** is the indirect spin–spin coupling tensor. Both **D** and **J** are general second-rank tensors. While **D** is traceless, **J** in general has a non-zero trace. Thus, in isotropic fluids where molecules tumble rapidly, the direct-dipolar coupling interaction generally does not influence the nuclear magnetic resonance (NMR) line shape of spins *N* or *N'*; however, as will be described below, the indirect interaction generally results in splitting(s), J_{iso} , in the NMR spectrum of both the spins *N* and *N'*.

It is often convenient to simplify equation (1) by separating the isotropic portion, J_{iso} , of the indirect spin–spin coupling from the traceless anisotropic portion, **J_T**,

$$E_{N,N'} = hJ_{\text{iso}}\mathbf{I}_N \cdot \mathbf{I}_{N'} + h\mathbf{I}_N \cdot (\mathbf{D} + \mathbf{J}_T) \cdot \mathbf{I}_{N'} \quad (2)$$

where J_{iso} is 1/3 the trace of **J** (simply the average value of the three diagonal elements of the **J**-tensor), often called the scalar coupling. The sign of J_{iso} may be positive or negative depending on the detailed electronic and molecular structure of the fragment under consideration and the signs of the magnetogyric ratios γ_N and $\gamma_{N'}$. If the sign of J_{iso} is positive, the lowest energy configuration of the two coupled nuclear magnetic moments is antiparallel provided that γ_N and $\gamma_{N'}$ have the same sign. In general, solution NMR spectra are insensitive to the absolute sign of J_{iso} .

It is instructive to consider the case of a heteronuclear diatomic molecule, for example, ^{35}Cl – ^{19}F , where the principal axis system (PAS) is defined by the C_∞ symmetry axis of the molecule. In this case, both the anisotropic **D** and **J_T**-tensors take a very simple form,

$$\mathbf{D} = R_{\text{DD}} \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -2 \end{bmatrix} \text{ and } \mathbf{J}_T = -\frac{\Delta J}{3} \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -2 \end{bmatrix} \quad (3)$$

where the direct dipolar coupling constant, R_{DD} , is defined by equation (4):

$$R_{\text{DD}} = \frac{\mu_0}{4\pi} \frac{\hbar}{2\pi} \gamma_N \gamma_{N'} \langle r_{NN'}^{-3} \rangle \quad (4)$$

and ΔJ is the anisotropy of the indirect spin–spin coupling tensor:

$$\Delta J = J_{\parallel} - J_{\perp} \quad (5)$$

Both R_{DD} and ΔJ are in frequency units, Hz; μ_0 is the permeability constant, $4\pi \times 10^{-7} \text{ kg m s}^{-2} \text{ A}^{-2}$, $\hbar$ is Planck's constant divided by 2π , and γ_N and $\gamma_{N'}$ are the magnetogyric ratios of nuclei *N* and *N'*, respectively. Equation (2) can be expressed as follows:

$$E_{NN'} = hJ_{\text{iso}}\mathbf{I}_N \cdot \mathbf{I}_{N'} + hR_{\text{eff}}\mathbf{I}_N \cdot \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -2 \end{bmatrix} \cdot \mathbf{I}_{N'} \quad (6)$$

where the effective dipolar coupling constant, R_{eff} , is $R_{\text{DD}} - \Delta J/3$. Equation (6) is general in that it demonstrates that one cannot separately measure R_{DD} and ΔJ . However, if one knows $r_{NN'}$ and can measure R_{eff} , then values of ΔJ can be obtained. Isotropic spin–spin coupling constants as small as 0.1 Hz are readily measured for small molecules in isotropic fluids. The largest known value of an isotropic indirect spin–spin coupling constant is $^1J(^{199}\text{Hg}, ^{199}\text{Hg})_{\text{iso}} = 284\,100 \pm 860 \text{ Hz}$ for $[\text{Hg}_2(18\text{-crown-6})(15\text{-crown-5})(\text{MeOH})](\text{O}_3\text{SCF}_3)_2$.¹

The purpose of this contribution is to focus on a discussion of the indirect spin–spin coupling. After a brief historic summary of the background theory, the symmetry properties of the **J**-tensor will be reviewed. Methods of characterizing **J**-tensors will be discussed and illustrated by several examples. Finally, some experimental and theoretical developments will be summarized.

2 THEORETICAL BACKGROUND

Experimental evidence of splittings due to indirect spin–spin coupling was first recognized in the NMR spectra of molecules in isotropic fluids. Several groups reported such splittings in the Physical Review in 1951.^{2–4}

Initial observations indicated that splittings in frequency units (Hz = cycles per second, cps, in the original NMR literature) due to spin–spin coupling were independent of the applied magnetic field. As well, splittings were found to be the same regardless of which nucleus was probed, N, or N'. For example, in the case of hydrogen deuteride, Carr and Purcell⁵ observed a doublet splitting of 43.5 ± 1 Hz in the ^2H NMR spectrum arising from deuterium transitions taking place with the ^1H (spin 1/2) either being $m_I = +1/2$ or $m_I = -1/2$. Similarly, the ^1H NMR spectrum appeared as three equally spaced peaks of equal intensity, each separated by 43.5 ± 1 Hz, corresponding to the deuterium nucleus (spin 1) being in any one of its three allowed spin states, $m_I = +1, 0, -1$.

Ramsey presented a comprehensive theory of indirect spin–spin coupling in 1953.⁶ Three interactions between nuclear spins and electron spins were identified as mechanisms for indirect nuclear spin–spin coupling,

$$\hat{\mathcal{H}}' = \hat{\mathcal{H}}_{1a} + \hat{\mathcal{H}}_{1b} + \hat{\mathcal{H}}_2 + \hat{\mathcal{H}}_3 \quad (7)$$

Here, $\hat{\mathcal{H}}_{1a}$ and $\hat{\mathcal{H}}_{1b}$ result from the interaction of the nuclear magnetic moment with the orbital magnetic moment of the electrons; $\hat{\mathcal{H}}_{1a}$ and $\hat{\mathcal{H}}_{1b}$ are known as the orbital ‘diamagnetic’ and ‘paramagnetic’ terms, respectively. $\hat{\mathcal{H}}_2$ represents the dipole–dipole interaction between the nuclear magnetic moment and the electron magnetic moment provided the electron does not reside at the nucleus (the “spin-dipolar” interaction), and $\hat{\mathcal{H}}_3$ is the Fermi-contact Hamiltonian which is non-zero when electrons have a finite probability of being at the nucleus. Ramsey’s second-order perturbation treatment lead to contributions of the form,

$$E_{\text{NN}'} (\text{indirect}) = \sum_n \frac{\langle \psi_0 | \hat{\mathcal{H}}' | \psi_n \rangle \langle \psi_n | \hat{\mathcal{H}}' | \psi_0 \rangle}{E_0 - E_n} \quad (8)$$

where the sum is over all excited states of the unperturbed system. Although the energy expression, in principle, contains cross terms, Ramsey showed that in the non-relativistic limit only cross terms between $\hat{\mathcal{H}}_2$ and $\hat{\mathcal{H}}_3$ are non-zero. Thus, the indirect spin–spin coupling tensor may be written as

$$\mathbf{J} = \mathbf{J}_{1a} + \mathbf{J}_{1b} + \mathbf{J}_2 + \mathbf{J}_3 + \mathbf{J}_4 \quad (9)$$

where $\mathbf{J}_4$ is the contribution due to the so-called spin-dipolar Fermi-contact cross term. The latter tensor has a zero trace but contributes to the anisotropy of the coupling tensor. In contrast, the Fermi-contact contribution, $\mathbf{J}_3$, is isotropic. The other terms make isotropic and anisotropic contributions to the total coupling tensor. Each of the contributions to $\mathbf{J}(\text{N}, \text{N}')$ are proportional to the product of the magnetogyric ratios, $\gamma_{\text{N}}\gamma_{\text{N}'}$, thus it is convenient to define a reduced indirect spin–spin coupling tensor which is independent of the nuclear magnetic moments:

$$\mathbf{K}(\text{NN}') = \frac{4\pi^2 \mathbf{J}(\text{NN}')}{h\gamma_{\text{N}}\gamma_{\text{N}'}} \quad (10)$$

where $\mathbf{K}$ has units of $\text{N A}^{-2} \text{m}^{-3}$ or equivalently $\text{T}^2 \text{J}^{-1}$ (SI units) or cm^{-3} (in cgs units). In the case of hydrogen deuteride, $^1J(^2\text{H}, ^1\text{H})_{\text{iso}} = 42.94 \pm 0.04 \text{ Hz}$ at 300 K ⁷ which corresponds to $^1K(\text{H}, \text{H})_{\text{iso}} = 2.329 \times 10^{20} \text{ T}^2 \text{J}^{-1}$ or $23.29 \times 10^{20} \text{ cm}^{-3}$.

Early theoretical calculations indicated that the Fermi-contact mechanism was largely responsible for indirect spin–spin coupling constants involving hydrogen nuclei. However, for molecules such as ClF, it is now known that both the paramagnetic orbital and spin-dipolar contributions to $^1\mathbf{K}(\text{Cl}, \text{F})$ are much greater than the Fermi-contact contributions.⁸ The expressions derived by Ramsey remain exact at the non-relativistic limit.⁹

A relativistic analogue of Ramsey’s theory of nuclear spin–spin coupling in molecules was presented by Pyykkö in 1977.¹⁰ A survey of the results using this theory and relativistically-parameterized extended Hückel calculations were presented by Pyykkö and Wiesenfeld in 1981.¹¹

More recently, Autschbach and Ziegler have presented a relativistic formulation of spin–spin coupling based on the two-component zeroth-order regular approximate (ZORA) Hamiltonian.¹² This formalism has been implemented into a density functional program which permits calculations on molecules containing heavy nuclei. Qualitatively, relativistic effects can be very important, even dominant, particularly if heavy nuclei are involved. Although electron orbital and spin moments are independent of each other in the non-relativistic limit, this is not the case when spin-orbit coupling (i.e., PSO) is significant. In such cases, the $\hat{\mathcal{H}}_{1b}$, $\hat{\mathcal{H}}_2$ cross term is non-zero and may be important.

Progress in the computation of indirect spin–spin coupling tensors is reviewed annually.¹³ For recent ‘state-of-the-art’ calculations of $\mathbf{J}$ -tensors for the hydrogen halides, see Visscher et al. and Vaara et al.¹⁴ Several recent reviews are highly recommended.^{15–18}

3 SYMMETRY PROPERTIES

As already mentioned, the indirect nuclear spin–spin coupling tensor is a general second-rank tensor, with up to nine independent components. The tensor may be decomposed into three parts: isotropic, J_{iso} , symmetric (J^{sym}), and antisymmetric (J^{antisym}).¹⁹

The isotropic component, a scalar, is one third the trace of $\mathbf{J}$. The symmetric part of the tensor is constructed from $\mathbf{J}$ and its transpose, $\mathbf{J}^t$,²⁰

$$\mathbf{J}^{\text{sym}} = \frac{(\mathbf{J} + \mathbf{J}^t)}{2} - J_{\text{iso}}\mathbf{1} \quad (11)$$

and may possess up to five independent components. In its principal axis system, $\mathbf{J}^{\text{sym}} + J_{\text{iso}}\mathbf{1}$ is diagonal and has up to three independent elements: J_{11} , J_{22} , and J_{33} , ordered according to the convention $|J_{33} - J_{\text{iso}}| \geq |J_{11} - J_{\text{iso}}| \geq |J_{22} - J_{\text{iso}}|$.²¹

The diagonalization of $\mathbf{J}^{\text{sym}} + J_{\text{iso}}\mathbf{1}$ yields its orientation in the molecular framework which may be defined by three Euler angles. The anisotropy of the indirect spin–spin coupling tensor, ΔJ , may be defined as,

$$\Delta J = J_{33} - \frac{J_{11} + J_{22}}{2} \quad (12)$$

For a tensor with only two unique principal components this reduces to equation (5). The asymmetry of the indirect spin–spin coupling tensor may be defined as

$$\eta = \frac{J_{22} - J_{11}}{J_{33} - J_{\text{iso}}} \quad (13)$$

where $0 \leq \eta \leq 1$. The antisymmetric portion of $\mathbf{J}$ is defined as,

$$\mathbf{J}^{\text{antisym}} = \frac{(\mathbf{J} - \mathbf{J}^t)}{2} \quad (14)$$

and may have up to three independent components.

The number of independent components of the $\mathbf{J}$ -tensor will depend on the symmetry properties of the molecule, and more specifically the local symmetry that is appropriate for the two coupled nuclei.²²

For CH_3F , the molecule belongs to the point group C_{3v} and the C–F bond lies along the principal axis; thus, there are only two unique components in the symmetric $\mathbf{J}^{(19\text{F}, 13\text{C})}$ -tensor. On the other hand, for the $\mathbf{J}^{(19\text{F}, 1\text{H})}$ -tensor, the relevant symmetry is C_s and it can be shown that the $\mathbf{J}$ -tensor has four symmetric components and one antisymmetric component. The number of non-vanishing symmetric and antisymmetric components of the indirect spin–spin coupling tensor when N and N' cannot be exchanged by symmetry (e.g., any heteronuclear spin-pair) is given in Table 1. More extensive discussions of symmetry rules for the indirect spin–spin coupling tensor have been given in the literature and are highly recommended.^{19,22,23} While experiments to characterize the antisymmetric component(s) have been proposed,^{19,20,24} successful measurements have not been reported. High-level first-principles calculations might be useful in suggesting appropriate molecules to investigate.²⁵ In the discussion that follows we will not consider the antisymmetric portion of the $\mathbf{J}$ -tensor further as it does not influence NMR spectra to first order.

4 CHARACTERIZATION OF J-TENSORS BY EXPERIMENT

Evidence for indirect spin–spin coupling and anisotropy in the $\mathbf{J}$ -tensor in a non-conducting solid was first inferred from ^{203}Tl and ^{205}Tl NMR measurements on powder samples of Tl_2O_3 .²⁶ The contribution of the ^{203}Tl – ^{205}Tl indirect spin–spin coupling anisotropy to the observed effective direct dipolar coupling was referred to as the ‘pseudo-dipolar’

Table 1 Number of Independent Components of the $\mathbf{J}$ -tensor for Some Important Group Symmetries (adapted from Ref.²²)^a

Point Group	Number of Unique Symmetric Components	Number of Unique Antisymmetric Components
C_1	6	3
C_s	4	1
C_2	4	1
C_{2v}	3	0
C_n ($n > 2$)	2	1
C_{nv} ($n > 2$)	2	0

^a Assuming the two nuclei are not exchanged by a symmetry operation.

character of the spin–spin coupling. In fact, any procedure for characterizing $\mathbf{J}$ -tensors involves experimentally measuring the effective dipolar tensor, $\mathbf{D} + \mathbf{J}_T$, and subtracting from it the direct dipolar tensor, $\mathbf{D}$. Clearly, knowledge of the direct dipolar tensor is required for any experimental characterization of the $\mathbf{J}$ -tensor. For isolated spin-pairs, the direct dipolar coupling tensor is readily calculated if the molecular structure is known (i.e., $\langle r^{-3} \rangle$). Accurate calculation of the dipolar tensor requires taking into account motional averaging (e.g., rovibrational averaging of R_{DD}).^{8,27}

In the solid-state physics literature (e.g., see Ref.²⁸), isotropic spin–spin coupling via conduction electrons is generally referred to as Ruderman–Kittel (RK) coupling.²⁹

Most experimental efforts to characterize the symmetric components of $\mathbf{J}$ -tensors have been confined to directly bonded spin-pairs that lie along a C_n -axis ($n > 2$) of symmetry. This ensures that the $\mathbf{J}$ -tensor is axially symmetric.

There are essentially three experimental techniques that may be used to characterize $\mathbf{J}$ -tensors: 1) high-resolution rotational spectroscopy including molecular beam magnetic resonance (MBMR) and molecular beam electric resonance (MBER),^{30,31} 2) nuclear magnetic resonance (NMR) studies of powder or single-crystal samples¹⁹ and 3) NMR studies of solutes in partially oriented fluids (i.e., liquid-crystalline solvents).³² An example illustrating an application of each of these techniques for deriving information on $\mathbf{J}$ -tensors will be described in the following section. In addition, strong electric fields can be used to partially align molecules in liquids with electric dipole moments.³³ This technique can also in principle be used to characterize $\mathbf{J}$ -tensors.³⁴ Buckingham and McLauchlan³⁵ demonstrated that partial alignment using electric fields can be used to determine the absolute sign of $^3J(^1\text{H}, ^1\text{H})_{\text{iso}}$ for *p*-nitrotoluene. Finally, anisotropy of the indirect spin–spin coupling could in principle provide a mechanism for nuclear spin relaxation in isotropic fluids²¹ but so far no experimental evidence for this mechanism exists.

4.1 Hyperfine Structure in High-Resolution Rotational Spectroscopy

The importance of molecular beam techniques to characterize $\mathbf{J}$ -tensors has not been well appreciated. Accurate experimental data are now available for more than 15 diatomic molecules⁸ (see Table 2 for a partial list). Since the measurements are performed on gaseous samples at very low pressures, the results from these experiments are important because they provide ‘benchmark’ data for isolated molecules that can be used to establish the reliability of first-principles calculations. For example, in the case of hydrogen fluoride, $^1J(^{19}\text{F}, ^1\text{H})_{\text{iso}} = +529 \pm 23$ Hz from gas phase measurements³⁶ while in acetonitrile solution, $^1J(^{19}\text{F}, ^1\text{H})_{\text{iso}} = +479 \pm 4$ Hz.³⁷ Clearly solvent effects on indirect spin–spin coupling constants can be significant, particularly in cases where intermolecular interactions are important.

To outline the molecular beam procedure for the characterization of indirect spin–spin coupling tensors, we will consider the diatomic molecule, ^{35}Cl – ^{19}F where the ^{35}Cl and ^{19}F nuclei are spin 3/2 and 1/2, respectively.^{38,39} In the absence of any external fields, the effective hyperfine Hamiltonian for this

^aRovibrational states: $\nu = 0, J = 0$ (LiF, LiI, BrF, IF); $\nu = 0, J = 1$ (LiH, LiBr, TlF, TlCl, ClF); $\nu = 0, J = 2$ (TlBr); $\nu = 0, J = 3$ (TlI).
^bsee reference 8 for references to the original literature.

molecule is generally expressed in the molecular beam literature as:^{30,31}

$$h^{-1}\hat{\mathcal{H}}_{\text{hf}} = \mathbf{V}_{\text{Cl}} \cdot \mathbf{Q}_{\text{Cl}} + c_{\text{Cl}} \mathbf{I}_{\text{Cl}} \cdot \mathbf{J} + c_{\text{F}} \mathbf{I}_{\text{F}} \cdot \mathbf{J} + c_3 \mathbf{I}_{\text{Cl}} \cdot \mathbf{d}_{\text{T}} \cdot \mathbf{I}_{\text{F}} + c_4 \mathbf{I}_{\text{Cl}} \cdot \mathbf{I}_{\text{F}} \quad (15)$$

The first term accounts for the ^{35}Cl nuclear quadrupolar interaction, c_{Cl} and c_{F} are the nuclear spin-rotation constants for ^{35}Cl and ^{19}F respectively, c_3 is the effective ^{35}Cl – ^{19}F dipolar coupling constant, and c_4 is $J(^{35}\text{Cl}, ^{19}\text{F})_{\text{iso}}$. The spin-rotation constants are related to the paramagnetic nuclear magnetic shielding and are important to those interested in absolute shielding tensors (see also **Chemical Shift Scales on an Absolute Basis**, Volume 2).^{40,41} For the $\nu = 0, J = 1$ state of ^{35}Cl – ^{19}F , Fabricant and Muentner³⁸ have reported $c_3 = 2859 \pm 9 \text{ Hz}$ and $c_4 = 840 \pm 6 \text{ Hz}$. Although the equilibrium bond length of the Cl–F molecule is known to more than five significant figures, one must make a rovibrational correction so that $\langle r^{-3} \rangle$ can be evaluated for the $\nu = 0, J = 1$ state. Procedures for carrying out rovibrational averaging in diatomics have been discussed by Bryce and Wasylishen⁸ and references therein. Using accepted values of the fundamental constants,⁴² $r = 1.6283323 \text{ \AA}$, $R_{\text{DD}} = 2557 \text{ Hz}$, thus $\Delta J/3 = -302 \pm 9 \text{ Hz}$ and $\Delta J = -906 \pm 27 \text{ Hz}$. Results for several other diatomics are presented in Table 2 and Ref.⁸ Consider the experimental results for the interhalogen fluorides: ^{35}ClF , ^{79}BrF , and ^{127}IF . As one descends the group 17 interhalogen fluorides, the magnitudes of K_{iso} and ΔK increase. Similarly for the thallium halides, the magnitudes of these parameters also increase as one descends group 17 (Table 2). This appears to be a general periodic trend.

4.2 Solid-state NMR Experiments

NMR investigations of $\mathbf{J}$ -tensors have been performed on both powder and single-crystal samples.^{19,43} Magic angle spinning (MAS) experiments²⁰ performed on samples containing spin–spin coupled spin-pairs readily provide J_{iso} ; however, analysis of the non-spinning samples is more difficult. For example, the ^{31}P NMR spectrum of $[\text{Ph}_3\text{P}-\text{PPh}_2][\text{GaCl}_4]$ acquired with MAS (Figure 1b) clearly demonstrates that

Figure 1 Phosphorus-31 NMR spectra of $[\text{Ph}_3\text{P}-\text{PPh}_2][\text{GaCl}_4]$ obtained at a spectrometer frequency of 161.98 MHz for (a) a stationary powder sample and (b) with magic angle spinning at 10.8 kHz

$|^1J(^{31}\text{P}_\text{A}, ^{31}\text{P}_\text{B})_{\text{iso}}| = 323 \pm 2 \text{ Hz}$. The corresponding spectrum acquired on a powder sample without MAS (Figure 1a) also consists of four transitions but is complicated by the orientation dependence of the phosphorus magnetic shielding of both nuclei as well as the direct-dipolar and anisotropic indirect ^{31}P , ^{31}P coupling interactions (vide infra). In the case of powder samples, it is difficult and often impossible to obtain reliable information about $\mathbf{J}$ -tensors unless the spin-pair of interest lies along a C_3 principal axis of a molecule which has C_{3v} or higher symmetry.

Here we discuss the powder NMR spectra of an isolated spin-pair where the two nuclei, A and X, are spin 1/2 nuclei and lie on the axis of symmetry such that both the nuclear magnetic shielding and the indirect spin–spin coupling tensors are axially symmetric and co-linear with the dipolar tensor. To predict the NMR spectra of such a spin system, we need to consider the following NMR Hamiltonian,

$$\hat{\mathcal{H}} = \hat{\mathcal{H}}_Z + \hat{\mathcal{H}}_{\text{CS}} + \hat{\mathcal{H}}_{\text{D}} + \hat{\mathcal{H}}_{\text{J}} \quad (16)$$

where $\hat{\mathcal{H}}_Z$ describes the interaction of the spins A and X with $\mathbf{B}_0$ and $\hat{\mathcal{H}}_{\text{CS}}$ describes the nuclear magnetic shielding interaction. Here we will focus on the NMR spectrum of the A spins. Together $\hat{\mathcal{H}}_Z$ and $\hat{\mathcal{H}}_{\text{CS}}$ may be written as:

$$\hat{\mathcal{H}}_Z + \hat{\mathcal{H}}_{\text{CS}} = \frac{h}{2\pi} \gamma_{\text{A}} \mathbf{I}_{\text{A}} \cdot (\mathbf{1} - \sigma_{\text{A}}) \cdot \mathbf{B}_0 \quad (17)$$

where σ_{A} is the nuclear magnetic shielding tensor. The direct and indirect spin–spin coupling Hamiltonians may be written:

$$\hat{\mathcal{H}}_{\text{D}} = \gamma_{\text{A}} \gamma_{\text{X}} \frac{h}{2\pi} \mathbf{I}_{\text{A}} \cdot \mathbf{D} \cdot \mathbf{I}_{\text{X}} \quad (18)$$

and

$$\hat{\mathcal{H}}_{\text{J}} = \gamma_{\text{A}} \gamma_{\text{X}} \frac{h}{2\pi} \mathbf{I}_{\text{A}} \cdot \mathbf{J} \cdot \mathbf{I}_{\text{X}} \quad (19)$$

As already mentioned, the magnetic shielding tensor for the systems considered must be axially symmetric with the $\sigma_{\parallel}$ and

$\sigma_{\perp}$ components corresponding to the shielding with $\mathbf{B}_0$ parallel and perpendicular to the A-X axis, respectively. The anisotropy or span of the magnetic shielding tensor may be defined as:

$$\Delta\sigma = \sigma_{\parallel} - \sigma_{\perp} \quad (20)$$

and the isotropic shielding, σ_{iso} , is $(2\sigma_{\perp} + \sigma_{\parallel})/3$. It is straightforward to show that the spectrum of the A spins is given by:

$$\begin{aligned} \nu_A = \nu_{\text{iso}} - \nu_{\text{iso}} \frac{\Delta\sigma}{3} (3\cos^2\theta - 1) \\ + m_X R_{\text{eff}} (3\cos^2\theta - 1) - m_X J_{\text{iso}} \end{aligned} \quad (21)$$

where ν_{iso} is $\gamma_A B_0(1 - \sigma_{\text{iso}})/2\pi$, θ is the angle between $\mathbf{B}_0$ and the AX axis and $m_X = 1/2$ or $-1/2$ ^{43,44} (see also **Dipolar & Indirect Coupling Tensors in Solids**, Volume 3). In Figure 2, we consider three cases: a) all spin-spin coupling interactions are zero, b) $R_{\text{eff}} = 0$ with $J_{\text{iso}} = 4\nu_{\text{iso}}\Delta\sigma$, and c) as above, except $R_{\text{eff}} = (\nu_{\text{iso}}\Delta\sigma)/3$. Spectrum 2a corresponds to the spectrum one would observe if the X-spins were decoupled. The discontinuity on the left corresponds to $\sigma_{\perp}$ while the shoulder on the right corresponds to $\sigma_{\parallel}$. In the hypothetical case where $R_{\text{eff}} = 0$ (Figure 2b), it is clear that the effect of J_{iso} is to produce two identical sub-spectra, one corresponding to $m_X = -1/2$ (on the left) and the other corresponding to $m_X = +1/2$ (on the right). Here we have assumed J_{iso} is positive. With $R_{\text{eff}} \neq 0$ (Figure 2c), the two sub-spectra now become different, one powder-pattern is stretched while the other is squeezed. Using equation (21) it is easy to demonstrate that the sub-spectrum corresponding to $m_X = +1/2$ becomes isotropic when $R_{\text{eff}} = \nu_{\text{iso}}\Delta\sigma/3$. If $R_{\text{eff}} > \nu_{\text{iso}}\Delta\sigma/3$, then the sense of the low-frequency sub-spectrum is opposite that of the high-frequency sub-spectrum. Note that in order to calculate the powder patterns one must average over all orientations of the A-X axis with respect to $\mathbf{B}_0$.^{21,45}

To illustrate an example where equation (21) may be used to extract ΔJ , consider the ^{31}P NMR spectra of the

Figure 2 Line shape for the A spin NMR spectrum of an AX spin-pair in a stationary powder sample, (a) where the X spins are decoupled, hence only the magnetic shielding interaction is present. If $R_{\text{eff}} = 0$ Hz and $J_{\text{iso}} = 4\nu_{\text{iso}}\Delta\sigma$ spectrum (b) is obtained. If $R_{\text{eff}} = (\nu_{\text{iso}}\Delta\sigma)/3$ and $J_{\text{iso}} = 4\nu_{\text{iso}}\Delta\sigma$, spectrum (c) is predicted. The spectra were calculated using $J_{\text{iso}} = 36$ kHz, $R_{\text{eff}} = 3$ kHz, and an axially symmetric nuclear magnetic shielding tensor with $\nu_{\text{iso}}\Delta\sigma = 9$ kHz

Figure 3 Phosphorus-31 NMR spectrum of solid tribromo(tris(4-methoxyphenyl)phosphine)indium(III), $\text{Br}_3\text{In-P[4-(CH}_3\text{O)C}_6\text{H}_4\text{]}_3$ obtained at a spectrometer frequency of 81.033 MHz. The spectrum was acquired with CP and magic angle spinning at 3.0 kHz

^{115}In - ^{31}P spin-pair in a powder sample of tribromo(tris(4-methoxyphenyl)phosphine)indium(III), $\text{Br}_3\text{In-P[4-(CH}_3\text{O)C}_6\text{H}_4\text{]}_3$ shown in Figures 3 and 4. Indium-115 has a natural abundance of 95.72% and a spin of 9/2. X-ray diffraction measurements indicate that the In-P bond lies along a C_3 axis and the In-P bond length is 2.583 Å, thus $R_{\text{DD}} = +623$ Hz.⁴⁶ The ^{31}P NMR spectrum obtained with rapid spinning about the magic angle is shown in Figure 3. Magic-angle spinning averages the phosphorus shielding and the effective ^{115}In , ^{31}P dipolar coupling tensor leaving only splittings due to J_{iso} . The equal spacing of all pairs of adjacent peaks indicates that the high-field approximation is reasonable here (i.e., the ^{115}In nuclei are quantized along $\mathbf{B}_0$).^{47,48} This spacing, 1109 ± 9 Hz, corresponds to $^1J(^{115}\text{In}, ^{31}\text{P})_{\text{iso}}$, and there are ten peaks in the spectrum because there are $2I_X + 1$ allowed values of m_X . The ^{31}P NMR spectrum of a stationary sample is shown in Figure 4. Noting the frequencies of the peak maxima in Figure 4(a) and comparing these frequencies with those in Figure 3, consideration of equation (21) indicated that $-9/2R_{\text{eff}} \simeq \nu_{\text{iso}}\Delta\sigma/3$. Spectral simulation shows that $R_{\text{eff}} = \pm 230 \pm 50$ Hz, thus $\Delta J = +1179 \pm 150$ Hz or -2559 ± 150 Hz corresponding to R_{eff} being positive or negative, respectively. Since analysis of the spectrum of the stationary sample indicated that $^1J(^{115}\text{In}, ^{31}\text{P})_{\text{iso}}$ and R_{eff} have the same signs and given that $^1K(\text{P}, \text{B})_{\text{iso}}$ is positive in analogous compounds, it is reasonable to assume that ΔJ is positive and therefore the value of $+1179 \pm 150$ Hz is preferred. The squeezing and stretching of each of the isotropic transitions in the calculated spectrum are illustrated for the ten transitions in Figure 4(c) and for just the $m_X = -9/2$ (to high frequency) and the $m_X = +9/2$ (to low frequency) sub-spectra in Figure 4(d).

The indirect spin-spin coupling tensor involving ^{115}In and ^{31}P has also been measured in the semiconductor material,

Figure 4 Phosphorus-31 NMR spectra of solid tribromo(tris-(4-methoxyphenyl)phosphine)indium(III), $\text{Br}_3\text{In}\cdot\text{P}(\text{4-(CH}_3\text{O)C}_6\text{H}_4)_3$ obtained at a spectrometer frequency of 81.033 MHz. The experimental spectrum (a) was acquired with CP using a stationary powder sample. The calculated powder line shape is shown in (b) with the sub-spectra shown in (c). For clarity, the sub-spectra corresponding to just the $m_x = -9/2$ (to high frequency) and $m_x = +9/2$ (to low frequency) indium-115 spin states are shown in (d)

InP, by Pines et al.⁴⁹ The magnitude of $^1J(^{115}\text{In}, ^{31}\text{P})_{\text{iso}}$ for undoped InP is 225 ± 10 Hz while $\Delta J = 1220 \pm 75$ Hz or 2600 ± 75 Hz, the two possible values arising because the absolute sign of R_{eff} could not be determined.

For a spin-pair of a quadrupolar nucleus coupled to a spin-1/2 nucleus, R_{eff} can often be derived from the spin-1/2 NMR spectra obtained with MAS. For example, consider the $^{63}\text{Cu}\text{--}^{31}\text{P}$ and $^{65}\text{Cu}\text{--}^{31}\text{P}$ spin-pairs of a bisphosphine of Cu(I) where the phosphine ligands are related by a center of inversion.⁵⁰ Both naturally occurring isotopes of copper, ^{63}Cu and ^{65}Cu , are spin 3/2 with natural abundances of 69.09 and 30.91%, respectively. In this case, the high-field approximation does not hold and the heteronuclear dipolar interaction is not completely averaged by MAS.⁴⁷ For example at 4.7 T, the Larmor frequency for ^{63}Cu is approximately 53.1 MHz and the nuclear quadrupolar coupling constant, $C_Q(^{63}\text{Cu})$, for $[\text{P}(\text{Bz})_3]_2\text{Cu}[\text{PF}_6]$ is 82.96 MHz. In this case, the calculated ^{31}P NMR spectra are sensitive to R_{eff} and hence to ΔJ (see Figure 5). Simulations of experimental ^{31}P NMR spectra acquired under MAS conditions at three different applied magnetic fields demonstrated that $^1J(^{63}\text{Cu}, ^{31}\text{P})_{\text{iso}} = +1550 \pm 10$ Hz and $\Delta J(^{63}\text{Cu}, ^{31}\text{P}) = +720 \pm 50$ Hz. A related ^{199}Hg NMR study of $\text{K}_2\text{Hg}(\text{CN})_4$ provided information about the **J**-tensor over two bonds; $|^2J(^{199}\text{Hg}, ^{14}\text{N})_{\text{iso}}| = 20.6$ Hz and

Figure 5 Phosphorus-31 NMR spectra calculated at 4.7 T for $[\text{P}(\text{Bz})_3]_2\text{Cu}[\text{PF}_6]$ spinning at the magic angle, showing the sensitivity of the line shape to the sign and magnitude of $\Delta J(^{63/65}\text{Cu}, ^{31}\text{P})$. The experimental spectrum corresponds to that calculated with $\Delta J(^{63}\text{Cu}, ^{31}\text{P}) = +720$ Hz⁵⁰

$\Delta^2J(^{199}\text{Hg}, ^{14}\text{N}) = 69 \pm 15$ Hz.⁵¹ Again, this measurement of ΔJ is possible because the high-field approximation breaks down for ^{14}N ($I = 1$).

In cases where both A and X are spin-1/2 nuclei, R_{eff} can also readily be obtained from slow-spinning MAS experiments provided that $J(\text{A}, \text{X})_{\text{iso}}$ is well-resolved and the intensities of several sidebands in each sub-spectrum of either the A- or the X-spin NMR spectrum can be measured. Consider Figure 2(c) where the span or breadth of each 'A' sub-spectrum is very different. Clearly, under conditions of MAS, the spinning sideband pattern of each sub-spectrum could be analyzed to obtain the principal components of each sub-spectrum using the Herzfeld–Berger method.⁵² Harris, Packer, and Thayer⁵³ have provided a detailed account of the background theory necessary to analyze such a spin system. Grossmann et al.⁵⁴ have recently applied this technique to measure $\Delta^1J(^{77}\text{Se}, ^{31}\text{P})$ in trimethyl and triphenyl phosphine selenide. Earlier, Penner, Power, and Wasylishen⁵⁵ applied this technique to measure $\Delta^1J(^{199}\text{Hg}, ^{31}\text{P})$ in a 1:1 mercury phosphine complex. Initial results obtained for powder samples were later verified by single-crystal ^{31}P NMR experiments involving a related compound.⁵⁶

A discussion of the single-crystal NMR experiments as applied to AX spin systems and mercury phosphine complexes was presented in the Encyclopedia of NMR (see **Dipolar & Indirect Coupling Tensors in Solids**, Volume 3).

For homonuclear spin-pairs, **J**-tensors have been characterized using single-crystal NMR.^{57,58} For powder samples, a 2D spin-echo experiment provides valuable information about R_{eff} .^{57,59} As well, slow spinning at the magic angle⁶⁰ (see

Figure 6 Phosphorus-31 NMR spectrum of a phosphole tetramer at 4.7 T. The sample spinning frequency was 1.5 kHz and the isotropic chemical shifts of P_A and P_B differ by 1.7 ppm. The asterisk indicates the average position of $\delta_{iso}^1 J(^{31}P, ^{31}P)_{iso} = -362$ Hz and $R_{eff} = 1.80 \pm 0.05$ kHz. The exact line shape and intensities of the numerous spinning sidebands shown here are very sensitive to the magnitudes and relative orientations of the shielding and dipolar tensors. See Ref.⁶⁰ for details

Figure 6) or fast spinning off the magic angle⁶¹ can also provide information about R_{eff} .

Finally, numerous dipolar recoupling experiments⁶² have been devised to ‘determine’ $r_{NN'}$; however, it is important to note that these experiments measure R_{eff} and not R_{DD} . Furthermore, the principal axis system of the direct dipolar tensor may not be coincident with the indirect spin–spin coupling tensor unless dictated by molecular symmetry.

4.3 Partially Oriented Fluids

In an applied magnetic field, the molecules of liquid crystalline solvents become partially aligned. As a result, the motion of solute molecules in such a medium becomes anisotropic and their resulting NMR spectra become dependent on both the anisotropic magnetic shielding and the intramolecular spin–spin coupling tensors ($\mathbf{D} + \mathbf{J}$); intermolecular dipole–dipole interactions are nearly averaged to zero. In liquid crystal NMR experiments, one must determine the degree of orientation of the solute molecules with respect to the magnetic field, which is described by one or more order parameters.^{32,63} Similar to solid-state NMR investigations of powder samples, reliable measurements of ΔJ are generally impossible without high symmetry. As an example of a ‘state-of-the-art’ investigation of a $\mathbf{J}$ -tensor using liquid-crystal NMR, we refer the reader to recent papers involving methylfluoride, CH_3F .^{64,65} To obtain $\Delta^1 J(^{19}F, ^{13}C)$, one requires the motionally averaged direct dipolar coupling constant corrected for harmonic and anharmonic vibrations. Also, a correction due to solvent deformations must be made in order to obtain reliable values of ΔJ .⁶⁶ For CH_3F , $^1 J(^{19}F, ^{13}C)_{iso} = -163$ Hz and

$\Delta^1 J(^{19}F, ^{13}C) = 350$ Hz; high-level ab initio calculations yield -156.6 Hz and 207.8 Hz, respectively, for these parameters.

The liquid crystal technique used for characterizing $\mathbf{J}$ -tensors was reviewed in 1982³² and in the Encyclopedia of NMR (see **Anisotropy of Shielding & Coupling in Liquid Crystalline Solutions**, Volume 2). A comprehensive review on $\mathbf{J}$ -tensors is currently being prepared.¹⁷

5 CONCLUSIONS

From the brief overview presented here it should be clear that it is possible to experimentally characterize the symmetric portion of indirect spin–spin coupling tensors. The accuracy of any experimental determination of a $\mathbf{J}$ -tensor is dependent on the experimentalist’s ability to characterize the accompanying direct-dipolar tensor. As indicated in sections 3 and 4 the reliability of $\mathbf{J}$ -tensor data will improve if the spin-pairs of interest lie on a principal axis of symmetry. In systems where symmetry does not require the dipolar and $\mathbf{J}$ -tensors to be coincident, most experimental techniques yield $\mathbf{J}$ -tensor data that are ambiguous at best, the exception being single-crystal NMR experiments.

Over the past few years there have been significant advances in the computation of $\mathbf{J}$ -tensors using both ab initio and density functional methods.^{13,17} Observation of J -coupling across hydrogen bonds⁶⁷ in nucleic acid base pairs has led to a renewed interest in ‘through-space’ indirect spin–spin coupling.⁶⁸

Many NMR experiments have been developed to measure dipolar coupling constants in solids under conditions of magic angle spinning. In these so-called “dipolar-recoupling” experiments it is important to recognize that one obtains R_{eff} . While the assumption that $R_{DD} = R_{eff}$ may be valid for many systems, there is growing evidence that $\Delta J/3$ can be significant particularly if heavy nuclei are involved in the spin–spin coupling. Finally, it is intriguing that magnetic field oriented media and residual dipolar couplings are being used to determine the structure of biomolecules.⁶⁹ Thus there is an apparent merging of traditional high-resolution solution-state NMR and solid-state NMR. Clearly some appreciation or knowledge of $\mathbf{J}$ -tensors is beneficial to a wide audience of NMR spectroscopists.

1 INTRODUCTION

Where an isotopic label is introduced into a molecule, every neighboring resonant nucleus experiences a slight chemical shift. If the labeling is less than 100%, the resonant nuclei in both the labeled and the unlabeled molecules are observed, with intensities according to statistical distribution. The magnitude of the shift depends on the fractional mass change at the isotope substitution site, on the remoteness of the resonant nucleus from the substitution site, and on the sensitivity of the shielding of the resonant nucleus. Every resonant nucleus in the isotopically labeled molecule experiences this chemical shift due to isotopic substitution, but the shift is only observable under favorable conditions, such as when the shift is larger than the halfwidth of the peaks. Isotope shifts as small as a few ppb have been observed, from zero bonds (the isotopic label itself is the resonant nucleus) to 12 bonds away from the substitution site.¹⁻³ When the isotopic label itself is the resonant nucleus, the isotope shift is called a primary isotope shift. Such primary isotope shifts can only be observed indirectly, when two in different molecules are compared. There are also attendant effects on the spin-spin coupling constants in the molecule.⁴ Here, the primary and secondary effects have to be deduced from the proper combination of observed couplings, and it is more appropriate to do this in the reduced coupling constant from which the gyromagnetic ratios have been removed altogether.

Isotope effects on chemical shifts and coupling constants are very important in two distinct ways. First, they have a multitude of practical applications, such as in the determination of molecular structure and the verification of mechanisms of reactions. This is just one more powerful tool in which a very selective tag carries with it the same wealth of information as the chemical shift itself. Second, isotope shifts provide a more stringent test of *ab initio* calculations of chemical shifts in specific molecules, being directly related to the slopes on the shielding surface (a mathematical surface), and, in a more general sense, the trends in the thousands of isotope shifts that have been accumulated¹⁻³ provide insight into the general

nature of these shielding surfaces, in terms of the dependence of the details of the surface on the nature of the chemical bond, the net charge of the molecule, bond orders, presence of lone pairs, etc.^{5,6} Isotope effects on coupling constants lack practical applications, but are invaluable from the second point of view. For the most part, coupling constants are obtained in rapidly tumbling systems, and only the isotropic average of the tensor is obtained. The full tensor is very difficult to extract from experiments in oriented molecules, since it is always observed as a sum with the larger dipolar tensor. Since coupling mechanisms other than the Fermi contact mechanism are the ones that give rise to the anisotropy of the tensor, the lack of tensor information leaves us with a severe dearth of critical tests of the *ab initio* calculations. Isotope effects on coupling constants provide additional critical tests, since they depend on the spin-spin coupling surface, not just a single calculated value. The earliest questions asked of theoretical calculations of chemical shifts demanded only that the relative order of chemical shifts be reproduced and that the relative magnitudes agree with experiment. More recently, we have asked how well the calculations reproduce the absolute shielding in specific molecules, not just their relative shifts, and also how well they reproduce the shielding tensor components. These are more stringent tests of theory. In the isotope shift experiments, we ask for even more detailed agreement: how well do the calculations reproduce the shapes of the shielding surfaces as the nuclear coordinates are displaced away from the immediate vicinity of the equilibrium geometry of the molecule? A similar question is posed for the spin-spin coupling surface by the primary and secondary isotope effects on J .

2 ISOTOPE SHIFTS: OBSERVATIONS

We follow the notation introduced by Gombler⁷ for the isotope shift observed for nucleus A upon substitution of the neighboring m' X isotope:

$${}^n\Delta A(m'/m \text{ X}) = \frac{\nu_A(A \ m'X \dots) - \nu_A(A \ mX \dots)}{\nu_A(A \ mX \dots)} \quad (m')m \quad (1)$$

where $\nu_A(A \ m'X \dots)$ is the resonance frequency of the A nucleus in the molecule having the heavier m' X isotope, which is n bonds away from the observed nucleus. The molecules $(A \ m'X \dots)$ and $(A \ mX \dots)$ are isotopomers. The isotope shift can also be written in terms of the nuclear shielding difference:

$$\begin{aligned} {}^n\Delta A(m'/m \text{ X}) &= \sigma^A(A \ mX \dots) - \sigma^A(A \ m'X \dots) \\ &= \sigma - \sigma^* \end{aligned} \quad (2)$$

where the asterisk applies to the heavy isotopomer. Just as for spin-spin couplings, this notation becomes ambiguous when A and X are atoms in cyclic compounds in which there are at least two paths connecting the observed nucleus and substituted atom, in which case the observed quantity is an isotope shift corresponding to two or more bond paths.

There are several general observations that have been made about magnitudes and signs of isotope shifts:^{1,8}

1. Upon substitution with a heavier isotope, the NMR signal of the nearby nucleus usually shifts towards lower frequencies (higher shielding). Thus, as defined in equations (1) and (2), isotope shifts are generally negative in sign.
2. The magnitude of the isotope shift depends on how remote the isotopic substitution is from the observed nucleus. Although there are exceptions, one-bond isotope shifts are larger than two-bond or three-bond shifts. In the examples shown in Table 1, there is a clear attenuation of the isotope shift with the number of bonds separating the NMR nucleus and the substitution site.^{9,10}
3. The magnitude of the isotope shift is a function of the observed nucleus, and reflects its chemical shift range. Comparisons can be made in analogous compounds, as in Table 2.
4. The magnitude of the shift is related to the fractional change in mass upon isotopic substitution. The larger the fractional change in mass, $(m' - m)/m'$, the larger the isotope shift, as is obvious in the examples in Table 3. (The signals can be easily assigned according to the abundance of the masses m' and m .) When two different atoms can be substituted in the molecule, the isotopic shifts are commensurate with the fractional change in masses, as in the example in Table 4.
5. The magnitude of the shift is approximately proportional to the number of equivalent atoms that have been substituted by isotopes. In other words, isotope shifts exhibit additivity. When there are multiple equivalent sites and the labeling is less than 100%, the resonant nuclei in the variously labeled and the unlabeled molecules are observed. For example, for a deuterium fraction d (based on the solvent isotopic composition for the exchange), for N equivalent replaceable hydrogens, the statistical limit for the relative intensity of the $\text{XH}_{N-n}\text{D}_n$ isotopomer will be

$$I_n = \frac{N!}{n!(N-n)!} (1-d)^{(N-n)} d^n \quad (3)$$

This strictly statistical formula neglects any isotope effects on the equilibrium constant for the exchange. By doing more than one labeling experiment (using different heavy atom fractions), the identification of the signals with the isotopomers can be unequivocal. Fortunately, in many cases, there is also spin–spin coupling information in the NMR spectrum, so that only one labeling experiment is necessary. When there are several equivalent substitution sites, the additivity of the isotope shifts is obvious, as in the examples in Table 5.^{15–18} Deviations from strict additivity are small, and their 0:3:4:3:0 ratio in CH_4 -like systems has been explained.¹⁹ Additivity is observed in long-range isotope shifts as well. For example, the two-bond deuterium-induced isotope shifts of ^{59}Co in hexaamminecobalt(III) chloride are all -5.2 ppm per D in each of the 18 different isotopomers of $[\text{Co}(\text{NH}_3)_6]^{3+}$. Less obvious, but also observed, is the additivity of isotope shifts due to substitution at nonequivalent sites.

^{183}W in $\text{CpWH}(\text{CO})_3$	−10.0	11500

These are the general trends found for all isotope shifts. These general experimental trends provide the testing grounds for the theory of isotope shifts. There are also some tendencies that are less global in nature but that are perceived as correlations in observations of related classes of compounds; for example, one-bond isotope shifts tend to be larger when the bond order between the observed nucleus and the substituted nucleus is higher. These correlations have to be considered separately, since they involve comparisons between different molecules that have many differences other than in the parameters that are being correlated with the isotope shifts.

3 ROVIBRATIONAL THEORY OF ISOTOPE SHIFTS

The effects of intramolecular dynamics (vibration and rotation) on nuclear shielding were theoretically predicted by Ramsey,²⁰ and have been observed in two ways. First, there is an observable temperature dependence of the resonance frequency, even for the ‘isolated’ molecule (apart from the temperature dependence due to intermolecular interactions). Second, there is an observable shift upon isotopic substitution of neighboring nuclei. Both are effects of differences in averaging over nuclear configuration as the molecule undergoes vibration and rotation.²¹ The temperature dependence of nuclear shielding is observed in the dilute gas phase.^{22–25} The nuclear shielding in an ‘isolated’ molecule, $\sigma_0(T)$, is an average of the nuclear magnetic shielding tensor over all possible orientations of the molecule in the magnetic field, and is actually observed as the nuclear shielding in the limit as the pressure approaches zero. One does not extrapolate the results to a true zero pressure, but to a pressure so low that collisional deformation of the molecule no longer contributes to σ , while there are still enough collisions to provide the required rate of transition between vibrational and rotational states. Thus, $\sigma_0(T)$ is an average over all possible rovibrational states of

Table 3

[CpVH(CO) ₃] [−]	2	1	$^1\Delta^{51}\text{V}(^{2/1}\text{H}) = -4.7$
	13	12	$^1\Delta^{51}\text{V}(^{13/12}\text{C}) = -0.51$

the molecule, weighted according to the fraction of molecules occupying that state at that temperature.

The average shielding for a given rovibrational state is different for each of several isotopically related species, because the masses enter into the solution of the vibrational–rotational Hamiltonian.²⁶ Thus, the thermal average shielding $\sigma_0(T)$ is different for the isotopomers. These differences are measured as isotope shifts. It is important to know which aspects of isotope shifts are due to dynamical factors (rovibrational averaging of internuclear separations) and which can be attributed to electronic factors (changes in nuclear shielding with bond extension or bond angle deformation). If the theory can sort out the former, isotope shifts can be used to extract the latter, thus providing chemically interesting information that would establish the isotope shift as an easily measurable index of the chemical bond.

3.1 Vibrational Averaging in Diatomic Molecules

The potential energy surface (PES) of a diatomic molecule can be written in terms of a Dunham potential, or more approximately in terms of a Morse potential. The Dunham potential function expresses the potential energy in terms of a Taylor series expansion in $x = (r - r_e)/r_e$:

$$V = a_0x^2(1 + a_1x + a_2x^2 + a_3x^3 + \dots) \quad (4)$$

The potential parameters $a_0, a_1, \dots$ can be obtained from the spectroscopic constants of the molecule. The vibrational levels and functions shown in Figure 1 for the H_2^+ molecule are typical. The first thing to note is that the anharmonic nature of the potential function leads to an unsymmetrical probability distribution function: there is a higher probability of finding the diatomic molecule extended than compressed. Second, this asymmetry becomes more pronounced as we move up in the potential well. Third, the vibrational levels for D_2^+ (shown also as dashed lines) lie lower in the potential well than those for H_2^+ , corresponding to its lower vibrational frequency,

$\omega_e = 1643.0 \text{ cm}^{-1}$ for D_2^+ compared with 2323.5 cm^{-1} for H_2^+ . Since we are interested in vibrational averaging and the mass dependence of shielding, we show in Figure 2 the vibrational functions of D_2^+ and H_2^+ . It is obvious that the anharmonic potential will give rise to different vibrational averages for the isotopomers, since the more sharply peaked and compact probability density of D_2^+ should lead to a different average than that for H_2^+ , in which the probability density is more spread out at the larger separations. This is true for the vibrational ground state, and the differences become even more pronounced at higher vibrational levels. The average values $\langle x^n \rangle$ can be obtained. Complete calculations for some isotopomers of H_2^+ lead to the results for the ground vibrational state shown in Table 6, which also shows the results for the case where the vibration is truly that of a harmonic oscillator (HO).

In order to observe more easily the largest terms that contribute to the above equations and explicitly express their mass dependence, we write only the leading terms, expressed in the measured spectroscopic constants of the molecule.⁸

$$\langle x \rangle_{\text{vJ}} = -3(v + \frac{1}{2})a_1 \frac{B_e}{\omega_e} + 4J(J+1) \frac{B_e}{\omega_e^2} \quad (5)$$

$$\langle x^2 \rangle_{\text{vJ}} = 2(v + \frac{1}{2}) \frac{B_e}{\omega_e} \quad (6)$$

Of these quantities, a_1 is mass-independent, and the others depend on the reduced mass of the diatomic molecule as follows:

$$\omega_e^* = \left(\frac{\mu}{\mu^*}\right)^{1/2} \omega_e, \quad B_e^* = \frac{\mu}{\mu^*} B_e \quad (7)$$

Furthermore, the thermal average $\langle v + \frac{1}{2} \rangle^T$ is also mass-dependent, since the populations of the vibrational energy levels over which this average is taken depend on the vibrational frequency ω_e . Note that B_e/ω_e^2 is mass-independent, so the rotational contribution to the thermal average shielding in the diatomic molecule is independent of mass.

Note also that if we include only the leading terms then

$$\langle x \rangle_{\text{v}} = -\frac{3}{2}a_1 \langle x^2 \rangle_{\text{v}} \quad (8)$$

The difference between two isotopomers is

$$\langle x^2 \rangle_{\text{vJ}} - \langle x^2 \rangle_{\text{vJ}}^* = 2 \frac{B_e}{\omega_e} \left[1 - \left(\frac{\mu}{\mu^*}\right)^{1/2} \right] (v + \frac{1}{2}) + \dots \quad (9)$$

4 ISOTOPE EFFECTS ON CHEMICAL SHIFTS AND COUPLING CONSTANTS

	NH_3D^+	-0.3077	-0.2933	+0.0144
	NH_2D_2^+	-0.6048	-0.5865	+0.0183
	NHD_3^+	-0.8937	-0.8798	+0.0139
	ND_4^+	-1.1730	-1.1730	0
^{13}C	CH_4	0.0	0.0	0
	CH_3D	-0.2016	-0.19865	+0.003
	CH_2D_2		-0.3973	
	CHD_3	-0.6006	-0.5960	+0.004
	CD_4	-0.7946	-0.7946	0

$$\langle x \rangle_{\text{vJ}} - \langle x \rangle_{\text{vJ}}^* = -3a_1 \frac{B_e}{\omega_e} \left[1 - \left(\frac{\mu}{\mu^*} \right)^{1/2} \right] \left(v + \frac{1}{2} \right) + \dots \quad (10)$$

The leading term in $\langle x^3 \rangle_{\text{vJ}}$ has the same mass dependence as the next higher order term in $\langle x \rangle$ and $\langle x^2 \rangle$; thus, it is consistent to include only the above two terms. We find the ratios from the full calculations:

$$\frac{\langle x \rangle_{\text{H}_2^+} - \langle x \rangle_{\text{HT}^+}}{\langle x \rangle_{\text{H}_2^+} - \langle x \rangle_{\text{HD}^+}} = 1.370 \quad (11)$$

$$\frac{\langle x^2 \rangle_{\text{H}_2^+} - \langle x^2 \rangle_{\text{HT}^+}}{\langle x^2 \rangle_{\text{H}_2^+} - \langle x^2 \rangle_{\text{HD}^+}} = 1.369 \quad (12)$$

whereas using *only* the leading terms leads in both cases to the ratio

$$\frac{1 - (\mu_{\text{H}_2^+}/\mu_{\text{HT}^+})^{1/2}}{1 - (\mu_{\text{H}_2^+}/\mu_{\text{HD}^+})^{1/2}} = 1.370 \quad (13)$$

Qualitatively, the mass change accompanying the replacement of ^mX by its heavier isotope $^{m'}\text{X}$ leads to a shorter average

bond length. In Figure 2, we show for the lowest vibrational levels the probabilities of finding the diatomic molecule at the various internuclear separations. For the same anharmonic potential, the lighter isotopomer H_2^+ clearly shows greater probabilities of being found in a more extended configuration compared with D_2^+ at each vibrational state. Since the vibrational frequencies are lower for the heavier isotopomer, the populations of its higher vibrational states are somewhat greater. Both effects constitute the mass dependence of the thermal average $\langle x \rangle^{\text{T}}$, with the latter being less important than the former:

$$\{\langle x \rangle^{\text{T}} - \langle x \rangle^{*\text{T}}\} \approx -3a_1 \frac{B_e}{\omega_e} \left[1 - \left(\frac{\mu}{\mu^*} \right)^{1/2} \right] \left(v + \frac{1}{2} \right)^{\text{T}} \quad (14)$$

If we use a harmonic oscillator density of vibrational states, we get a simple form

$$\left(v + \frac{1}{2} \right)_{\text{HO}}^{\text{T}} = \frac{1}{2} \coth(hc\omega_e/2k_{\text{B}}T) \quad (15)$$

which itself has a mild mass dependence, which is not too important when ω_e is large, in which case $\coth(hc\omega_e/2k_{\text{B}}T)$

Table 6

$x = (r - r_e)/r_e$	H_2^+	HD^+	HT^+	D_2^+

Figure 1 Vibrational levels and wavefunctions (squared) for the H_2^+ molecule. Also shown, by dashed lines, are the vibrational levels of the D_2^+ molecule

is very close to 1. A useful form of an approximate potential for the diatomic molecule is the Morse function

$$V = D_e \{1 - \exp[-a(r - r_e)]\}^2 \quad (16)$$

where D_e is the dissociation energy and a is called the Morse parameter, ar_e being a dimensionless quantity related to the ratio

$$\frac{1}{3!} \left(\frac{d^3 V}{dx^3} \right)_e \bigg/ \frac{1}{2!} \left(\frac{d^2 V}{dx^2} \right)_e = -ar_e = a_1 \quad (17)$$

and

$$\langle x \rangle = \frac{3}{2} ar_e \langle x^2 \rangle \quad (18)$$

At this level of theory, the mass dependence of $\langle x^2 \rangle$ is the same as that of $\langle x \rangle$. Thus, we find that for diatomic molecules, neglecting the mass dependence in the coth function,

$$\begin{aligned} \langle x \rangle^T - \langle x \rangle^{*T} &\approx \frac{3ar_e}{2} \frac{B_e}{\omega_e} \left[1 - \left(\frac{\mu}{\mu^*} \right)^{1/2} \right] \coth \left(\frac{hc\omega_e}{2k_B T} \right) \\ &\approx \langle x \rangle^T \left[1 - \left(\frac{\mu}{\mu^*} \right)^{1/2} \right] \end{aligned} \quad (19)$$

or

$$\langle \Delta r \rangle^T - \langle \Delta r \rangle^{*T} \approx \langle \Delta r \rangle_{\text{vib}}^T \left[1 - \left(\frac{\mu}{\mu^*} \right)^{1/2} \right] \quad (20)$$

Figure 2 Vibrational wavefunctions (squared) for the D_2^+ molecule (heavy lines) and the H_2^+ molecule (light lines)

$$\langle \Delta r \rangle_{\text{vib}}^T \approx \frac{3ar_e^2}{2} \frac{B_e}{\omega_e} \coth \left(\frac{hc\omega_e}{2k_B T} \right) \quad (21)$$

When μ/μ^* is very close to 1 (which is true for most situations not involving hydrogen), $1 - (\mu/\mu^*)^{1/2}$ can be further approximated by $(\mu^* - \mu)/2\mu^*$ or, in the comparison of the isotopomers A^mX and $\text{A}^{m'}\text{X}$, by²⁷

$$1 - \left(\frac{\mu}{\mu^*} \right)^{1/2} \approx \frac{1}{2} \frac{(m' - m)}{m'} \frac{m_A}{(m_A + m)} \quad (22)$$

$$\langle \Delta r \rangle^T - \langle \Delta r \rangle^{*T} \approx \langle \Delta r \rangle_{\text{vib}}^T \frac{1}{2} \frac{(m' - m)}{m'} \frac{m_A}{(m_A + m)} \quad (23)$$

with an analogous expression for $\langle (\Delta r)^2 \rangle$. Here we find already the origin of general trend 4 in Section 2. The dynamic factors contain the mass dependence, and in diatomic molecules this mass dependence takes a simple form. It is interesting to point out here that, even for polyatomic molecules, this mass dependence has been found to hold: for $m'/m \text{SeF}_6$, a plot of $\langle \Delta r_{\text{SeF}} \rangle^T$ and $\langle (\Delta r_{\text{SeF}})^2 \rangle^T$ versus $(m' - m)/m'$ for $m = 74$ and $m' = 76, 77, 78, 80, 82$ leads to straight lines passing through the origin.²⁸

A very interesting global description of potential functions for diatomic molecules was given by Herschbach and Laurie.²⁹ They found that the second and third derivatives of the potential could be described by exponential functions of the equilibrium internuclear distance, each described by a family of curves which are determined by the locations of the bonded atoms in rows of the Periodic Table:

$$(-1)^n F_n = 10^{-(r_e - p_n)/q_n} \quad (24)$$

where

$$F_3 \equiv \frac{1}{3} \left(\frac{d^3 V}{dr^3} \right)_e, \quad F_2 \equiv \left(\frac{d^2 V}{dr^2} \right)_e \quad (25)$$

and p_n and q_n are parameters that characterize any two rows of the Periodic Table. It was proposed by Jameson and Osten²⁷ that the averages $\langle x \rangle_v$ and $\langle x^2 \rangle_v$ can be determined entirely from a knowledge of the r_e and the rows of the Periodic Table to which the atoms belong, using the following relations:

$$\langle \Delta r \rangle_v = r_e \langle x \rangle_v \approx \frac{3h}{8\pi} \mu^{-1/2} 10^{-D} (2v + 1) \quad (26)$$

$$\langle (\Delta r)^2 \rangle_v = r_e^2 \langle x^2 \rangle_v \approx \frac{h}{4\pi} \mu^{-1/2} 10^{-d} (2v + 1) \quad (27)$$

where

$$D \equiv \frac{r_e - p_3}{q_3} - \frac{3(r_e - p_2)}{2q_2} \quad (28)$$

$$d \equiv \frac{r_e - p_2}{2q_2} \quad (29)$$

Figure 3 shows a plot of $\langle \Delta r \rangle_{\text{vib}}$ calculated at 300 K for a large set of diatomic molecules using their individual spectroscopic constants. It appears that the global relation given in equation (26) provides a reasonably good description of the vibrationally averaged bond displacement for diatomic molecules. It has been shown that these equations can be used as well to estimate the dynamic parts for polyatomic molecules, except that the constant factor is closer to $\frac{3}{7}$ than $\frac{3}{8}$.

3.2 The Shapes of Shielding Surfaces

In the context of the Born–Oppenheimer approximation, analogous to the potential energy surface, which is a mass-independent electronic property of a molecule in a given electronic state, there is likewise a mass-independent nuclear shielding surface that describes the variation of the shielding as a function of nuclear configuration. For a diatomic molecule, this surface can be described entirely in terms of the internuclear separation. Two examples are shown in Figures 4 and 5. At the united atom limit ($r = 0$), the diamagnetic shielding of the He^+ ion is (not shown) 35.5009 ppm. At the equilibrium geometry of H_2^+ , the proton shielding is 11.4296 ppm, and at the separated atom limit, the diamagnetic shielding corresponds to half that of the free hydrogen atom ($\frac{1}{2}$) 17.75 ppm.³⁰ The other example is ^{23}Na shielding in NaH, in which the shielding at the equilibrium geometry is lower than for the separated system (either Na^+ or Na atom).³¹ Figure 4 is a typical shielding surface for diatomic molecules in that the shielding surface has negative first and second derivatives.^{32,33} For example, ^{19}F in the HF molecule and in the F_2 molecule, and ^{35}Cl in the HCl molecule and in the ClF molecule, all have negative first and second derivatives; that is, deshielding accompanies bond extension. It is also typical for the proton shielding in the molecule at its equilibrium geometry to be greater than that for the free H atom in the separated systems. On the other hand, the heavy nuclei

Figure 3 Mean bond displacement in diatomic molecules calculated by vibrational averaging over their individual potential surfaces compared with the global form $\langle \Delta r \rangle_{\text{vib}} \approx (3h/8\pi) \mu^{-1/2} 10^{-D}$ (the straight line), where D is defined in equation (28). (Reproduced by permission of the American Institute of Physics from Jameson and Osten²⁷)

are generally deshielded in the molecule at its equilibrium geometry compared with the diamagnetic shielding of the free atom. For example, nearly all ^{19}F nuclei have shielding less than 470.71 ppm. (^{19}F in ClF is a notable exception, and ^{19}F in CH_3F has an isotropic shielding nearly the same as that of the free F atom.) Every ^{19}F shielding first derivative at the equilibrium geometry, including ^{19}F in the ClF molecule, has been found to be negative, and the second derivative is negative as well.³⁴ On the other hand, the shielding surfaces for ^{23}Na in NaH and ^7Li in LiH have positive first derivatives at the equilibrium geometry.³¹ The shapes of the shielding surfaces in Figures 4 and 5 are fairly similar; the major difference is which point on the shielding surface corresponds to the pocket in the PES and to which side of the shielding minimum this point corresponds. We have seen that the general behavior in vibrational averaging in the anharmonic PES is that the probabilities are greater on the $r > r_e$ side. Thus, dynamic averaging always leads to deshielding when the pocket in the PES is to the short- r side of the shielding minimum, whereas dynamic averaging leads to increased shielding relative to the shielding at the equilibrium geometry when the pocket in the PES is to the longer- r side of the shielding minimum. Most nuclei that are observed in NMR are found on the right-hand side of the Periodic Table, where the shielding surface and the PES are related as in Figure 4; there are fewer observations of the alkali and alkaline earth nuclei, whose shielding surfaces and PES are related as in Figure 5. Therefore, the usual case

Figure 4 The ^1H shielding surface for the H_2^+ molecule is shown with the potential energy surface. The shielding surface is from ab initio calculations by Hegstrom.³⁰ (Reproduced by permission of the American Institute of Physics from Jameson and de Dios³¹)

is more like Figure 4. Here then is the explanation for general trend 1 in Section 2: superposition of Figure 2 on Figure 4 would lead to a nucleus in the lighter isotopomer being less shielded than the same nucleus in the heavy isotopomer. Preponderance of this situation would lead to a nearly universal sign of one-bond isotope shifts. The exceptions will be Li and Na in the hydrides, for example.

The magnitudes of the isotope shifts would correspond to the ranges of chemical shifts of the observed nucleus if the shielding surfaces themselves scale to these. Let us see. We present the shielding surfaces in the vicinity of the equilibrium geometry in analogous compounds in Figure 6, where ^{19}F in F_2 is compared with ^{35}Cl in ClF (both are bonded to fluorine). ^{19}F in HF is compared with ^{35}Cl in HCl (both are bonded to an H atom). Finally, ^{23}Na in NaH is compared with ^7Li in LiH . It is found that if the change in shielding, $\sigma(r) - \sigma(r_e)$, is scaled by the factor $r_e \langle a_0^3/r^3 \rangle$, the equilibrium bond distance in the molecule and the purely electronic quantity $\langle a_0^3/r^3 \rangle$ characteristic of the atom, for the observed nucleus, the surfaces that describe the change in the shielding of different nuclei in analogous bonding situations superimpose.³¹ This then is an explanation for general trend 3 in Section 2: the magnitude of the isotope shift is a function of the observed nucleus and reflects its chemical shift range. A general discussion of shielding surfaces is given by de Dios and Jameson.³⁵

3.3 Averaging Over Shielding Surfaces

It is sometimes actually necessary to evaluate the average over a large part of the shielding surface.³⁶ For example, the

Figure 5 The ^{23}Na shielding surface for the NaH molecule is shown with the potential energy surface. The shielding surface is from ab initio calculations by Jameson and de Dios. (Reproduced by permission of the American Institute of Physics from Jameson and de Dios³¹)

PES of the NH_3 molecule has a rather broad double minimum in the inversion coordinate. The trace on the ^{15}N shielding surface along this inversion coordinate is shown in Figure 7. To obtain the contribution to the average ^{15}N shielding from this degree of freedom, it was necessary to find the numerical PES (which are highly anharmonic) and solve for the vibrational wavefunctions. These are shown in Figure 7. The average for each state 0^s , 0^a , 1^s , 1^a , 2^s , 2^a was numerically calculated with these functions, $\langle \Psi_v | \hat{\sigma} | \Psi_v \rangle$, and the thermal average is obtained as

$$\langle \sigma \rangle^T = \frac{\sum_v e^{-E_v/k_B T} \langle \sigma \rangle_v}{\sum_v e^{-E_v/k_B T}} \quad (30)$$

For semirigid molecules that we often observe in NMR (excluding molecules that are fluxional or that undergo low-frequency torsion), the motions involved in the averaging take place in a small pocket of the potential energy surface close to the equilibrium configuration. It is therefore not necessary to calculate the entire shielding surface, as we have shown in Figures 4, 5, and 7. In the same way that averages such as $\langle x \rangle$, $\langle x^2 \rangle$, $\langle x^3 \rangle$, etc. could be evaluated in terms of the derivatives of the PES such as represented by the quantities a_0 , a_1 , a_2 , a_3 , etc. in the Dunham potential function, it is possible to calculate the average shielding from derivatives of the shielding surface at the equilibrium geometry, since we only need to average over very small displacements away from the minimum in the PES.

Figure 6 The shielding surfaces of analogous diatomic molecules in the vicinity of the equilibrium geometry, in the range of nuclear displacements spanning the classical turning points of the ground vibrational state. (Reproduced by permission of the American Institute of Physics from Jameson and de Dios³¹)

For a diatomic molecule, it is convenient to expand the shielding surface as a power series in $x = (r - r_e)/r_e$. For a particular molecular state characterized by vibrational and rotational quantum numbers v and J ,

$$\langle \sigma \rangle_{vJ} = \sigma_e + \left(\frac{d\sigma}{dx} \right)_e \langle x \rangle_{vJ} + \frac{1}{2} \left(\frac{d^2\sigma}{dx^2} \right)_e \langle x^2 \rangle_{vJ} + \dots \quad (31)$$

Here $\langle x \rangle_{vJ}$, $\langle x^2 \rangle_{vJ}$, ... are the averages over the vibrational-rotational wavefunctions corresponding to the (v, J) level, which we have already described in Section 3.1. The isotope shift is therefore given by

$$\begin{aligned} \langle \sigma \rangle^T - \langle \sigma \rangle^{*T} &= \left(\frac{d\sigma}{dx} \right)_e (\langle x \rangle^T - \langle x \rangle^{*T}) \\ &+ \frac{1}{2} \left(\frac{d^2\sigma}{dx^2} \right)_e (\langle x^2 \rangle^T - \langle x^2 \rangle^{*T}) + \dots \end{aligned} \quad (32)$$

With the approximations described in Section 3.1, using the Morse parameter,

Figure 7 The ^{15}N shielding surface of NH_3 along the inversion coordinate β (the angle between the symmetry axis and a N–H bond) is shown with the vibrational wavefunctions for the lowest inversion levels. The shielding average can be obtained by numerical integration as $\langle \sigma \rangle_v = \int \Psi_v^*(\beta) \sigma(\beta) \Psi_v(\beta) d\beta$. (Reproduced by permission of the American Institute of Physics from Jameson et al.³⁶)

$$\langle x \rangle^T \approx \frac{3}{2} a r_e \langle x^2 \rangle^T \quad (33)$$

the isotope shift in diatomic molecules is given by

$$\begin{aligned} \langle \sigma \rangle^T - \langle \sigma \rangle^{*T} &\approx \left[\left(\frac{d\sigma}{dx} \right)_e + \frac{1}{3ar_e} \left(\frac{d^2\sigma}{dx^2} \right)_e \right] (\langle x \rangle^T - \langle x \rangle^{*T}) + \dots \\ &\approx \left[\left(\frac{d\sigma}{dr} \right)_e + \frac{1}{3a} \left(\frac{d^2\sigma}{dr^2} \right)_e \right] (\langle \Delta r \rangle^T - \langle \Delta r \rangle^{*T}) \end{aligned} \quad (34)$$

and, when $\coth(hc\omega_e/2k_B T)$ is close to 1,

$$\begin{aligned} \langle \sigma \rangle^T - \langle \sigma \rangle^{*T} &\approx \left[\left(\frac{d\sigma}{dr} \right)_e + \frac{1}{3a} \left(\frac{d^2\sigma}{dr^2} \right)_e \right] \\ &\times \langle \Delta r \rangle_{\text{vib}}^T \left[1 - \left(\frac{\mu}{\mu^*} \right)^{1/2} \right] \end{aligned} \quad (35)$$

In equations (34) and (35), the first quantity (in square brackets) is a mass-independent purely electronic quantity; the second quantity is a mass-dependent dynamic factor. As we have seen, both the first and second derivatives of the shielding surface are most often negative. Right here, we see that the sign of the isotope shift is negative owing to $(d\sigma/dr)_e$ being negative, since the shift is defined such that the dynamic factor is positive; that is, the nucleus in the light isotopomer is less shielded (appears at higher frequency) than the nucleus in the heavy isotopomer. The unusual (positive) sign of the isotope shift will be observed when the shielding derivative is positive, such as for ^{23}Na in NaH or ^7Li in LiH . For polyatomic molecules, it makes physical sense to expand the nuclear shielding in terms of the normal coordinates Q_s (a concept of significance only for small displacements):^{21,37}

$$\sigma = \sigma_e + \sum_s \left(\frac{\partial \sigma}{\partial Q_s} \right)_e Q_s + \frac{1}{2} \sum_{s,r} \left(\frac{\partial^2 \sigma}{\partial Q_r \partial Q_s} \right)_e Q_r Q_s + \dots \quad (36)$$

where the shielding derivatives are taken at the equilibrium configuration. Normal coordinates are a logical choice for this expansion, since methods of evaluating the average values $\langle Q_s \rangle$ and $\langle Q_r Q_s \rangle$ are well known in vibrational spectroscopy. However, the derivatives of the nuclear shielding with respect to the mass-dependent normal coordinates are not invariant under isotopic substitution. For the purpose of discussing the isotope shift, it is more convenient to expand the shielding in terms of mass-independent internal displacement coordinates:^{5,21}

$$\sigma = \sigma_e + \sum_i \left(\frac{\partial \sigma}{\partial \mathcal{J}_i} \right)_e \mathcal{J}_i + \frac{1}{2} \sum_{ij} \left(\frac{\partial^2 \sigma}{\partial \mathcal{J}_i \partial \mathcal{J}_j} \right)_e \mathcal{J}_i \mathcal{J}_j + \dots \quad (37)$$

where $\mathcal{J}_i$ stands for the bond displacements (Δr_i) and the bond angle deformations $(\Delta \alpha_{ij})$.

The theoretical interpretation of isotope shifts in polyatomics therefore involves the mass-independent electronic quantities such as

$$\left(\frac{\partial \sigma}{\partial \mathcal{J}_i} \right)_e = \left(\frac{\partial \sigma}{\partial \Delta r} \right)_e, \quad \left(\frac{\partial \sigma}{\partial \Delta \alpha} \right)_e, \quad \dots \quad (38)$$

which describe the change in nuclear shielding with bond extension or angle deformation, and the mass-dependent thermal averages $\langle \mathcal{J}_i \rangle^T$, which are $\langle \Delta r \rangle^T$, $\langle \Delta \alpha \rangle^T$, ... and $\langle \mathcal{J}_i \mathcal{J}_j \rangle^T$, which are $\langle (\Delta r)^2 \rangle^T$, $\langle (\Delta \alpha)^2 \rangle^T$, $\langle \Delta r \Delta \alpha \rangle^T$, The isotope shift is given by

$$\begin{aligned} \sigma - \sigma^* &= \sum_i \left(\frac{\partial \sigma}{\partial \mathcal{J}_i} \right)_e (\langle \mathcal{J}_i \rangle^T - \langle \mathcal{J}_i \rangle^{T*}) \\ &+ \frac{1}{2} \sum_{ij} \left(\frac{\partial^2 \sigma}{\partial \mathcal{J}_i \partial \mathcal{J}_j} \right)_e (\langle \mathcal{J}_i \mathcal{J}_j \rangle^T - \langle \mathcal{J}_i \mathcal{J}_j \rangle^{T*}) + \dots \end{aligned} \quad (39)$$

In order to be able to evaluate $\langle \mathcal{J}_i \rangle^T$, $\langle \mathcal{J}_i \mathcal{J}_j \rangle^T$ etc., we need a potential surface in which the vibrational motion of the molecule takes place. The known derivatives of this surface are the quadratic, cubic, etc. force constants. Normal coordinate analysis with the quadratic force constants gives the solutions to the harmonic problem, which are the harmonic frequencies ω_s , the normal coordinates Q_s , and the $\mathbf{L}$ matrix. The internal displacement coordinates $\mathcal{J} = \Delta r_j$, $\Delta \alpha_{ij}$, etc. can be expressed in terms of these normal coordinates in the general relation³⁸

$$\mathcal{J} = \mathbf{Q} \quad (40)$$

where is a tensor containing the transformation coefficients between the curvilinear internal coordinates and various powers of Q_s . The vibrational part of Δr_i is then

$$\Delta r_i = \sum_l L_i^l Q_l + \frac{1}{2} \sum_{r,s} L_i^{rs} Q_r Q_s + \frac{1}{6} \sum_{r,s,t} L_i^{rst} Q_r Q_s Q_t + \dots \quad (41)$$

Thus, the vibrational average $\langle \Delta r \rangle_{\text{vib}}$ can be expressed in terms of $\langle Q_r \rangle$, $\langle Q_r Q_s \rangle$, etc. The analytical expressions for elements of the $\mathbf{L}$ tensor are given by Hoy et al.,³⁸ in which the linear terms L_i^r are identical to the elements L_{ir} of the $\mathbf{L}$ matrix. The above equation is exact, but in practice, of course, the series must be truncated; in general, it converges well, each term being smaller than the preceding by a factor of about 10 for typical vibrational amplitudes. The expectation values of only totally symmetric coordinates Q_s are required:³⁹

$$\langle Q_s \rangle = \left(\frac{h}{4\pi^2 c} \right)^{1/2} \omega_s^{-3/2} \left[3k_{sss} \left(v_s + \frac{1}{2} \right) + \sum_r k_{srr} \left(v_r + \frac{1}{2} g_r \right) \right] \quad (42)$$

where ω_s are the normal frequencies and k_{srr} are the cubic force constants, both in wavenumbers. g_r denotes the degeneracy of the r th vibration. $\langle Q_r Q_s \rangle = 0$ if $\omega_r \neq \omega_s$, and

$$\langle Q_s^2 \rangle = \frac{h}{4\pi^2 c \omega_s} \left(v_s + \frac{1}{2} \right) \quad (43)$$

To obtain the thermal average shielding, we again need $\langle v_s + \frac{1}{2} \rangle^T$. For larger molecules, it becomes impossible to calculate a sufficient number of rovibrational states in order to use the exact method for the thermal averaging, so the only practical way of calculating expectation values of molecular properties over different rotational and vibrational states for a given temperature is by using the harmonic approximation for the vibrational partition function, that is,

$$\langle v_s + \frac{1}{2} \rangle^T = \frac{1}{2} \coth(hc\omega_s/2k_B T) \quad (44)$$

3.4 Relative Magnitudes of Terms That Contribute to the Isotope Shift

Mass substitution at one site in the molecule affects dynamic averages of all electronic properties. If, in particular, we have nuclear spins at various sites, all of these will have different average shifts; some will experience larger changes than others. In general, the entire molecule participates in the dynamic averaging. Depending on the nature of each nuclear shielding surface, the change in chemical shift may be of either sign. Each molecule offers a unique situation, and, especially for the long-range isotope effects, vibrations involving many atoms may play a part. To illustrate the types of terms that contribute to a one-bond isotope shift, we use the

$^1\Delta$ ^{13}C ($^{2/1}\text{H}$) in CH_4 as an example. During vibration, the displacements away from the equilibrium nuclear configuration can be small enough that a Taylor series expansion can be used:⁴⁰

$$\begin{aligned} \langle \sigma^{\text{C}} \rangle = & \sigma_{\text{e}} + P_r(\langle \Delta r_1 \rangle + \langle \Delta r_2 \rangle + \langle \Delta r_3 \rangle + \langle \Delta r_4 \rangle) \\ & + \frac{1}{2} P_{rr}[\langle (\Delta r_1)^2 \rangle + \langle (\Delta r_2)^2 \rangle + \langle (\Delta r_3)^2 \rangle + \langle (\Delta r_4)^2 \rangle] \\ & + P_{rs}(\langle \Delta r_1 \Delta r_2 \rangle + \langle \Delta r_1 \Delta r_3 \rangle + \langle \Delta r_1 \Delta r_4 \rangle \\ & + \langle \Delta r_2 \Delta r_3 \rangle + \langle \Delta r_2 \Delta r_4 \rangle + \langle \Delta r_3 \Delta r_4 \rangle) \\ & + \frac{1}{2} P_{\alpha\alpha}[\langle (\Delta \alpha_{12})^2 \rangle + \dots] + P_{\alpha\beta}(\langle \Delta \alpha_{12} \Delta \alpha_{13} \rangle + \dots) \\ & + P_{r\alpha}(\langle r_1 \Delta \alpha_{12} \rangle + \dots) + P_{\alpha\omega}(\langle \Delta \alpha_{12} \Delta \alpha_{34} \rangle + \dots) \\ & + \text{higher-order terms} \end{aligned} \quad (45)$$

where $P_r \equiv (\partial \sigma^{\text{C}} / \partial r_1)_{\text{e}}$, while P_{rr} and P_{rs} are the second derivatives of the ^{13}C shielding with respect to the C–H bond distances; $P_{\alpha\alpha}$, $P_{\alpha\beta}$, and $P_{\alpha\omega}$ are the second derivatives of the ^{13}C shielding with respect to the HCH bond angles, and $P_{r\alpha}$ is the mixed second derivative $(\partial^2 \sigma^{\text{C}} / \partial r_1 \partial \alpha_{12})_{\text{e}}$. In some molecules, there are first derivatives with respect to the angle as well, for example, for ^{17}O in H_2O and ^{31}P in PH_3 .^{41,42} In yet others, the averaging cannot be carried out by considering small displacements, as in the inversion motion of the NH_3 molecule. The complexity of the equation increases with increasing number of atoms. Nevertheless, many general trends may be observed in the huge body of information represented in tables of thousands of isotope shifts.^{1–3} These trends have become apparent, despite the uniqueness of the dynamic averaging of each molecule, because some terms in the full theory are more dominant than others. It is the persistence of the dominant contributions in most molecules that allows us to consider isotope shifts in much simpler terms, short of full averaging of full shielding surfaces in every case. In Table 7, we examine the relative magnitudes of terms that contribute to the isotope shift in selected molecules, where the calculations of the many terms (as shown above for CH_4) have been carried out to gain some insight into what might be expected in other molecules.^{36,42–46} Clearly, the mixed terms and higher-order terms (listed in Table 7 as ‘Other’) are negligible compared with the total isotope shift. The P_r term, which is due entirely to the anharmonicity of the vibration, provides the largest contribution, but P_{rr} terms are not negligible. The stretch (P_r and P_{rr} terms together) dominate, even in the case of NH_3 , where the inversion mode gives significant angle deformation contributions. If we can extrapolate these results to larger molecules, we can say that the bond stretching contributions dominate one-bond isotope shifts, and the anharmonic part of this, which goes with the first

Table 8 Comparison of Shielding Derivatives Estimated from Isotope Shifts with Those Obtained from Ab Initio Quantum Mechanical Calculations

	$(\partial \sigma / \partial r)_{\text{e}}$ (ppm $\text{\AA}^{-1}$)

^{15}N in NO_2^-	–990 ⁵¹	–1438.1 ³⁴
^{15}N in NO_3^-	–410 ⁵¹	–498.0 ³⁴

shielding derivative $(\partial \sigma / \partial r)_{\text{e}}$, gives the largest contribution. However, the terms involving the second derivative $(\partial^2 \sigma / \partial r^2)_{\text{e}}$ are also important. Bond angle contributions are uniformly less important than the bond stretching contributions to the isotope shift.

If we take the experimental isotope shift and use an estimate for the dynamic factor $\langle \Delta r_{\text{XH}} \rangle - \langle \Delta r_{\text{XD}} \rangle$, we arrive at a reasonable estimate of the shielding derivative $(\partial \sigma / \partial r)_{\text{e}}$ in the molecule. Indeed, Table 8 shows that the estimated shielding derivatives compare reasonably well with the derivatives obtained from the ab initio shielding surfaces.

3.5 Additivity of Isotope Shifts

We can use the isotopomers of the CH_4 molecule to illustrate the additivity of NMR isotope shifts. The mean bond displacements in the methane family $\text{CX}_{4-n}\text{Y}_n$ (where X, Y = H, D, T) have been calculated using the anharmonic force field of methane.¹⁹ It has been found that the substitution effects on the vibrational contribution to mean bond displacements are strictly additive. Each substitution of a hydrogen by a deuterium shortens the appropriate bond by nearly the same amount Δ . The mean bond displacements in $^{12}\text{CH}_{4-n}\text{T}_n$ and $^{12}\text{CD}_{4-n}\text{T}_n$ exhibit the same strictly linear dependence on n . We can express $\langle \Delta r_{\text{CH}} \rangle$ and $\langle \Delta r_{\text{CD}} \rangle$ in $^{12}\text{CH}_{4-n}\text{D}_n$ as follows. If we let

$$d = \langle \Delta r_{\text{CH}} \rangle \quad \text{in } \text{CH}_4 \text{ at } 300 \text{ K} \quad (46)$$

Table 7 Isotope Shifts $\sigma^{\text{X}}(\text{XH}_n) - \sigma^{\text{X}}(\text{XD}_n)$ (in ppm) Calculated for ^{13}C , ^{15}N , ^{31}P , ^{17}O , and ^{77}Se Nuclei

Term	CH_4 ⁴³	NH_3 ³⁶	PH_3 ⁴²	H_2O ⁴⁴	H_2Se ^a

^aCalculated by Jameson,⁴⁵ based on the points on the ab initio shielding surface of Tossell and Lazzeretti.⁴⁶

$$d - \Delta = \langle \Delta r_{CD} \rangle \quad \text{in } \text{CD}_4 \text{ at } 300 \text{ K} \quad (47)$$

where $d = 2.0881 \text{ pm}$ and $\Delta = 0.553 \text{ pm}$, we find for $\text{CH}_{4-n}\text{D}_n$ that

$$\langle \Delta r_{CD} \rangle = d - \Delta + (4 - n)\delta_D \quad (48)$$

$$\langle \Delta r_{CH} \rangle = d + n\delta_H \quad (49)$$

Similar relations can be found for the other series of isotopomers. That is, for a given bond, substitution of an isotope involved in this bond had an effect Δ on its own mean bond length (a primary effect on the mean bond displacement); each substitution of an isotope at some other bond has a much smaller effect δ (a secondary effect). The ^2H -induced ^{13}C NMR isotope shift between any two isotopomers of $\text{CH}_{4-n}\text{D}_n$ can then be expressed as

$$\begin{aligned} \sigma^C(\text{CH}_{4-n}\text{D}_n) - \sigma^C(\text{CH}_{4-n'}\text{D}_{n'}) &= \left(\frac{\partial \sigma^C}{\partial r} \right)_e \\ &\quad \times [(n' - n)\Delta + \text{terms in } \delta] \\ &\approx \left(\frac{\partial \sigma^C}{\partial r} \right)_e (n' - n)\Delta \end{aligned} \quad (50)$$

This is the basis for the near-additivity of isotope shifts due to substitution at equivalent sites. If we leave out the terms in δ (which are about two orders of magnitude smaller than Δ), we have strict additivity: the magnitude of the shift is proportional to the number $n' - n$ of atoms that have been substituted by isotopes. Even when all the terms in P_{rr} , P_{rs} , P_{rs} , etc. are included and calculated properly, the nearly strict additivity of isotope shifts is preserved. Although there are many smaller changes that are not quite the same as each ^mX is replaced by $^{m'}\text{X}$, it has been shown that these smaller changes lead to only slight deviations from additivity, which deviations incidentally have been observed^{15–18} just as predicted.¹⁹

4 GENERAL TRENDS IN THE ELECTRONIC FACTORS

We have already seen that the dynamical factors in one-bond isotope shifts are fairly predictable, and can even be estimated without a good force field because the mass-independent part of the dynamic factor is largely determined by the bond length and the rows of the Periodic Table of the pair of bonded atoms. We have also seen that the mass dependence of the isotope shift and its additivity can be explained entirely by the dynamic factors for one-bond isotope shifts. All other trends must therefore be attributable to trends in the electronic factor and the first and second derivatives of the nuclear shielding. If we estimate the dynamic factors $\langle \Delta r \rangle - \langle \Delta r \rangle^*$ as described in Section 3.1, it is possible to obtain the magnitudes and signs of the electronic factor $[(\partial \sigma / \partial r)_e + (1/3a)(\partial^2 \sigma / \partial r^2)_e]$, which we shall denote simply by $(\partial \sigma / \partial r)_e$, with the understanding that the first-derivative terms nearly always dominate, although the ratio of the above two terms may range from 10:1 to 3:1.

Some trends in $(\partial \sigma / \partial r)_e$ have been predicted from the observed trends in isotope shifts.^{5,6} Recent ab initio calculations have explored the generality of these trends and the limits and conditions of their applicability.³⁴

1. $(\partial \sigma / \partial r)_e$ is usually negative. The general shape of the shielding surface shown in Figure 4 seems to be typical for a diatomic molecule, and, for most nuclei, the minimum in the shielding surface occurs at separations larger than the equilibrium internuclear separation, leading to a negative $(\partial \sigma / \partial r)_e$. The exceptional sign of $(\partial \sigma / \partial r)_e$ arises when the minimum in the shielding surface lies inside the equilibrium internuclear separation, as in Figure 5. In polyatomic molecules, negative $(\partial \sigma / \partial r)_e$ are also much more commonly found than positive ones, leading to the usual (negative) sign of the isotope shift.
2. $(\partial \sigma / \partial r)_e$ generally increases with the chemical shift range of the nucleus. We have seen in Figure 6 that changes in the shielding upon displacement away from the equilibrium geometry do scale in analogous compounds according to $\langle a_0^3 / r^3 \rangle$ for the free atom, which is the same factor that varies periodically across the Periodic Table in the same way as the ranges of chemical shifts.^{54,55} Because of this correlation, an easy way to obtain an estimate of an isotope shift is to use the scaling factor of $\langle a_0^3 / r^3 \rangle$ values to provide a Periodic-Table-wide set of 'reduced isotope shifts', which need only be multiplied by the mass factors $[(m' - m)/m'] \times (m_A + m)/2m_A$ to get an estimate of the one-bond isotope shift induced by any isotopic substitution for any nucleus in any molecule.⁵⁶
3. $(\partial \sigma / \partial r)_e$ has been found to correlate with the absolute shielding σ_0 in related molecules: at the equilibrium geometry, the most deshielded environments have more steeply changing shielding surfaces. When the dynamic terms are very similar, this forms the basis for the correlations of $^1\Delta$ with chemical shifts, which have been observed in some cases. Such correlations of isotope shifts are more likely to be noticed in diatomic-like situations such as $^{13/12}\text{C}$ -induced ^{19}F isotope shifts or $^{18/16}\text{O}$ -induced ^{13}C isotope shifts in $\text{O}=\text{C}$ situations.⁵⁷ Chesnut and Wright have found that calculated shielding derivatives do roughly correlate with shielding itself for ^{19}F and for ^{13}C , ^{15}N , and ^{17}O involved in multiple bonds.
4. The magnitudes of the derivatives of shielding with respect to extension of a bond increase with increasing bond order. Since bond lengths tend to anticorrelate with bond order (higher bond order, shorter bond length), this trend in the shielding derivative is also the basis for the observed increasing magnitudes of one-bond isotope shifts for shorter bond lengths between the NMR nucleus and the substitution site.
5. The shielding derivative tends to be more negative with increasing negative net charge and with the presence of lone pairs on the observed nucleus. This has been found in the comparisons of ^{15}N in NO_2^- and NO_3^- , ^{15}N in NH_3 and NH_4^+ , ^{31}P in PH_4^+ , PH_3 and PH_2^- , ^{119}Sn in SnH_3^+ , SnH_4 and SnH_3^- , and ^{13}C and also ^{15}N in HCN and CN^- .
6. Since the one-bond coupling constant is a purely electronic quantity, it must be the electronic factors in the one-bond isotope shifts that allow the observation of linear correlations with the one-bond coupling constant, and likewise the incremental effects of substitution of H by Ph or H by CH_3 in the examples in Table 9.^{10–61} These above data translate to increasingly negative $(\partial \sigma^X / \partial r_{\text{XH}})_e$ upon successive Ph substitution at X.

5 ISOTOPE SHIFTS OVER TWO OR MORE BONDS

Isotope shifts due to substitution with a heavier atom at a site remote from the observed nucleus show the same general trends as one-bond isotope shifts.

1. The sign is still generally negative, although some are positive, with some alternation of signs being observed in the same molecule.
2. The magnitude reflects the chemical shift range of the observed nucleus.
3. The magnitude is related to the fractional mass change.
4. The effect is additive.

These are generally smaller than one-bond shifts; nevertheless, a large number of them have been observed, some over a distance of seven or more bonds. The question is, what information is contained in these long-range shifts? What we propose to show here is that these long-range shifts are a property of the electronic transmission path from the site of substitution up to the resonant nucleus.

To illustrate the types of terms that contribute to a long-range isotope shift, let us consider a two-bond isotope shift such as $^2\Delta^{13}\text{C}(^{2/1}\text{H})$ in CH_4 .¹⁹ The average proton shielding for proton H_1 can be written as

$$\begin{aligned}
 \langle\sigma^{\text{H}_1}\rangle &= \sigma_e + P_r\langle\Delta r_1\rangle + P_s(\langle\Delta r_2\rangle + \langle\Delta r_3\rangle + \langle\Delta r_4\rangle) \\
 &+ \frac{1}{2}P_{rr}(\langle\Delta r_1\rangle^2) + \frac{1}{2}P_{ss}[(\langle\Delta r_2\rangle^2) + (\langle\Delta r_3\rangle^2) + (\langle\Delta r_4\rangle^2)] \\
 &+ P_{rs}(\langle\Delta r_1\Delta r_2\rangle + \langle\Delta r_1\Delta r_3\rangle + \langle\Delta r_1\Delta r_4\rangle) \\
 &+ P_{st}(\langle\Delta r_2\Delta r_3\rangle + \langle\Delta r_2\Delta r_4\rangle + \langle\Delta r_3\Delta r_4\rangle) + \dots
 \end{aligned} \quad (51)$$

where

$$P_r \equiv \left(\frac{\partial\sigma^{\text{H}_1}}{\partial r_1}\right)_e, \quad P_s \equiv \left(\frac{\partial\sigma^{\text{H}_1}}{\partial r_2}\right)_e \quad (52)$$

and P_{rr} , P_{ss} , P_{rs} , and P_{st} are the appropriate second derivatives of the shielding with respect to the various C–H distances. Therefore, the two-bond deuterium-induced proton isotope shifts between CH_3D and CH_4 is (with D replacing proton number 2)

$$\begin{aligned}
 ^2\Delta^{13}\text{C}(^{2/1}\text{H}) &= \langle\sigma^{\text{H}_1}\rangle_{\text{CH}_4} - \langle\sigma^{\text{H}_1}\rangle_{\text{CH}_3\text{D}} \\
 &= (P_r + 2P_s)(\langle\Delta r_1\rangle_{\text{CH}_4} - \langle\Delta r_1\rangle_{\text{CH}_3\text{D}}) \\
 &+ P_s(\langle\Delta r_2\rangle_{\text{CH}_4} - \langle\Delta r_2\rangle_{\text{CH}_3\text{D}}) \\
 &+ (\frac{1}{2}P_{rr} + P_{ss})[(\langle\Delta r_1\rangle^2)_{\text{CH}_4} - (\langle\Delta r_1\rangle^2)_{\text{CH}_3\text{D}}] \\
 &+ \frac{1}{2}P_{ss}[(\langle\Delta r_2\rangle^2)_{\text{CH}_4} - (\langle\Delta r_2\rangle^2)_{\text{CH}_3\text{D}}] \\
 &+ (P_{rs} + 2P_{st})(\langle\Delta r_1\Delta r_2\rangle_{\text{CH}_4} - \langle\Delta r_1\Delta r_2\rangle_{\text{CH}_3\text{D}}) \\
 &+ (2P_{rs} + P_{st})(\langle\Delta r_1\Delta r_3\rangle_{\text{CH}_4} - \langle\Delta r_1\Delta r_3\rangle_{\text{CH}_3\text{D}}) \\
 &+ \dots
 \end{aligned} \quad (53)$$

With D replacing proton number 2, $\delta = \langle\Delta r_i\rangle_{\text{CH}_4} - \langle\Delta r_i\rangle_{\text{CH}_3\text{D}}$ is (the same for $i = 1, 3, 4$) a slight change of about 10^{-3} pm in the other C–H average bond lengths due to deuteration, and $\langle\Delta r_2\rangle_{\text{CH}_4} - \langle\Delta r_2\rangle_{\text{CH}_3\text{D}}$ is the typical $\Delta = \langle r_{\text{CH}} \rangle - \langle \Delta r_{\text{CD}} \rangle$, which is of order about 0.5 pm:

$$\begin{aligned}
 ^2\Delta^{13}\text{C}(^{2/1}\text{H}) &\approx (P_r + 2P_s)\delta + P_s\Delta + (\frac{1}{2}P_{rr} + P_{ss})\delta_{rr} + \frac{1}{2}P_{ss}\Delta_{rr} \\
 &+ (P_{rs} + 2P_{st})\Delta_{rs} + (2P_{rs} + P_{st})\delta_{rs}
 \end{aligned} \quad (54)$$

If we invoke the relationship $\langle\Delta r\rangle \approx \frac{3}{2}a r_e \langle(\Delta r)^2\rangle$ used earlier, we find

$$\begin{aligned}
 ^2\Delta^{13}\text{C}(^{2/1}\text{H}) &\approx \left(P_s + \frac{1}{3a}P_{ss}\right)\Delta + \left(P_r + \frac{1}{3a}P_{rr} + 2P_s + \frac{2}{3a}P_{ss}\right)\delta \\
 &+ \text{mixed terms} + \text{higher-order terms}
 \end{aligned} \quad (55)$$

or, more succinctly,

$$\begin{aligned}
 2\Delta^{13}\text{C}(^{2/1}\text{H}) &\approx \mathcal{S}\Delta + (\mathcal{P} + 2\mathcal{S})\delta \\
 &+ \text{mixed terms} + \text{higher-order terms}
 \end{aligned} \quad (56)$$

Here $\mathcal{P}$ stands for the following combination of primary first and second derivatives:

$$\mathcal{P} \equiv \left(\frac{\partial\sigma^{\text{H}_1}}{\partial r_1}\right)_e + \frac{1}{3a}\left(\frac{\partial^2\sigma^{\text{H}_1}}{\partial r_1^2}\right)_e \quad (57)$$

and is a measure of the sensitivity of the shielding of a nucleus to stretching of a bond to it. $\mathcal{S}$ stands for the following combination of secondary first and second derivatives:

$$\mathcal{S} \equiv \left(\frac{\partial\sigma^{\text{H}_1}}{\partial r_2}\right)_e + \frac{1}{3a}\left(\frac{\partial^2\sigma^{\text{H}_1}}{\partial r_2^2}\right)_e \quad (58)$$

and is a measure of the sensitivity of the shielding of a nucleus to stretching of a remote bond.¹⁹ When we recall that $\Delta \approx 0.5$ pm whereas $\delta \approx 10^{-3}$ pm, we see that the term $\mathcal{S}\Delta$ would dominate the isotope shift unless $\mathcal{P}$ is two orders of magnitude larger than $\mathcal{S}$. It is therefore valid to consider a long-range isotope shift as largely described by a product of a primary change in the average bond length at the heavy atom substitution site (the dynamic factor) and a secondary shielding derivative(s) that measures the change in shielding upon a change with bond length at the remote site. This is very encouraging, because the secondary dynamic factor δ is so dependent on the entire molecular framework and potential energy surface in which vibrations take place that it is difficult to estimate. On the other hand, we have seen that Δ has a very straightforward dependence on r_e and the masses in the local fragment, and can be easily estimated. This means that if the δ terms are unimportant, the sign and magnitude of the long-range isotope shifts are a direct measure of the sign and

magnitude of $(\partial\sigma/\partial r_{\text{remote}})_e$. This derivative is stereospecific, dependent on electron-withdrawing/donating abilities of substituents, and has the usual electronic-transmission-path dependence of various observables such as long-range spin-spin coupling and substituent effects on chemical shifts. Thus, in $^{13}\text{CH}_3(\text{CH}_2)_{n-2}\text{NHD}$, for example,

$${}^n\Delta^{13}\text{C}^{(2/1)}\text{H} \approx \left[\left(\frac{\partial\sigma^{\text{C}}}{\partial r_{\text{NH}}} \right)_e + \frac{1}{3a} \left(\frac{\partial^2\sigma^{\text{C}}}{\partial r_{\text{NH}}^2} \right)_e \right] \times (\langle\Delta r_{\text{NH}}\rangle - \langle\Delta r_{\text{ND}}\rangle) \quad (59)$$

it is easy to see why n -bond isotope shifts are in general smaller than one-bond isotope shifts. The farther away the substitution site is from the observed nucleus, the smaller the secondary derivative is expected to be. For example, in the H_2O molecule,⁴¹

$$\begin{aligned} \left(\frac{\partial\sigma^{\text{H}_1}}{\partial r_{\text{OH}_1}} \right)_e &= -0.353 \text{ ppm pm}^{-1} \\ \left(\frac{\partial\sigma^{\text{H}_1}}{\partial r_{\text{OH}_2}} \right)_e &= -0.046 \text{ ppm pm}^{-1} \end{aligned} \quad (60)$$

that is, a trace along the increasing coordinate r_{OH_1} gives a sharply decreasing H_1 shielding surface near the equilibrium geometry, but a trace along the coordinate r_{OH_2} on the same shielding surface is rather flat. Also, the nearly flat portion of the shielding surface could be sloping slightly in either direction; thus, either sign is possible for long-range isotope shifts. The secondary derivatives should still reflect the shielding sensitivity of various nuclei as manifested in the ranges of their chemical shifts.

The experimental evidence for the dominance of the term $S\Delta$ is convincing.

1. The observed additivity of long-range isotope shifts is completely consistent with this. Isotope shifts from equivalent substitution sites such as a remote CH_3 group involve the secondary derivative multiplied by one Δ term for each C–D replacing a C–H.
2. The mass dependence of the two-bond isotope shift is the same as that of the one-bond shift, that is, $1-(\mu/\mu^*)^{1/2}$, where μ and μ^* are the local reduced masses at the substitution site. Furthermore, the ratio of the effects of substitution of H by T to that of H by D is the same as would be expected if the Δ term dominated the isotope shift. Vibrational calculations show that⁴⁸

$$\frac{\langle\Delta r_{\text{CH}}\rangle_{\text{CH}_4} - \langle\Delta r_{\text{CT}}\rangle_{\text{CT}_4}}{\langle\Delta r_{\text{CH}}\rangle_{\text{CH}_4} - \langle\Delta r_{\text{CD}}\rangle_{\text{CD}_4}} = 1.426 \quad (61)$$

In $(\text{CH}_3)_2\text{C}=\text{O}$, the observed ratio of isotope shifts for tritium and deuterium substitution is¹¹

$$\frac{{}^1\Delta^{13}\text{C}^{(3/1)}\text{H}}{{}^1\Delta^{13}\text{C}^{(2/1)}\text{H}} = 1.424 \pm 0.025 \quad (62)$$

That this ratio is indistinguishable from 1.426 serves to reassure us that the leading term is dominant in one-bond shifts, with $(\partial\sigma/\partial r)_e (\langle\Delta r_{\text{CH}}\rangle - \langle\Delta r_{\text{CD}}\rangle)$ for deuterium substitution and $(\partial\sigma/\partial r)_e (\langle\Delta r_{\text{CH}}\rangle - \langle\Delta r_{\text{CT}}\rangle)$ for tritium substitution. The two-bond isotope shifts have also been observed in $\text{CH}_3^{13}\text{C}(\text{O})\text{CH}_3$, and these have the ratio¹¹

$$\frac{{}^2\Delta^{13}\text{C}^{(3/1)}\text{H}}{{}^2\Delta^{13}\text{C}^{(2/1)}\text{H}} = 1.41 \pm 0.12 \quad (63)$$

This ratio is also indistinguishable from 1.426, which indicates that the dominant contribution is $(\partial\sigma^{\text{C}(\text{O})}/\partial r_{\text{CH}})_e \times (\langle\Delta r_{\text{CH}}\rangle - \langle\Delta r_{\text{CT}}\rangle)$ for tritium substitution and $(\partial\sigma^{\text{C}(\text{O})}/\partial r_{\text{CH}})_e (\langle\Delta r_{\text{CH}}\rangle - \langle\Delta r_{\text{CD}}\rangle)$ for deuterium substitution.

3. The relative signs of one-bond and n -bond isotope shifts for the same nucleus in the same molecule are not always the same. Consider, for example, the carbonyl carbon isotope shifts in $(\text{CH}_3)_2^{13}\text{C}=\text{O}$. The ${}^1\Delta^{13}\text{C}^{(18/16)}\text{O}$ and ${}^2\Delta^{13}\text{C}^{(2/1)}\text{H}$ are opposite signs. Thus, the important term in ${}^2\Delta^{13}\text{C}^{(2/1)}\text{H}$ must not involve $(\partial\sigma^{\text{C}(\text{O})}/\partial r_{\text{CO}})_e \delta$.
4. The long-range isotope shifts correlate with indicators of electronic transmission paths such as dihedral angle dependence of three-bond isotope shifts (similar to the Karplus relation for three-bond coupling constants, although not with one set of coefficients), stereospecificity (*cis* versus *trans* versus *gauche*, and *syn* versus *anti*) of isotope shifts parallels that of spin-spin coupling, and the correlation of long-range isotope shifts with electron-withdrawing/donating ability of substituents, even across a path traversing seven bonds. These correlations of long-range isotope shifts with purely electronic quantities can only be observed if the isotope shift is itself dominated by an electronic factor that depends on the transmission of electronic information between the observed nucleus and the mass-modified site: a fortunate occurrence, since the long-range electronic factor is far more interesting and useful than the long-range dynamic factor. Since the primary dynamic factor Δ is easily estimated, long-range isotope shifts can provide direct invaluable information about the changes in shielding of a nucleus upon a minor perturbation at a distant site.

In summary, the electronic factor $(\partial\sigma^{\text{A}}/\partial r_{\text{XY}})_e$ in the long-range isotope shifts is found to have the following attributes.

1. The magnitude decreases (usually) as the Y–X bond becomes more remote from nucleus A. Ab initio calculations have shown that for the first- and second-row hydrides XH_n , the ratio $(\partial\sigma^{\text{H}_1}/\partial r_2)_e/(\partial\sigma^{\text{H}_1}/\partial r_1)_e = 0.06\text{--}0.14$. However, the two-bond secondary derivative is not necessarily much smaller than primary derivatives, especially when multiple bonds are involved.³⁴
2. It is stereospecific. For three-bond isotope shifts, it is found that *cis*, *trans* > *gauche*, and in some cases the dihedral angle dependence has been clearly observed and it is not unlike the Karplus relation of three-bond spin-spin coupling with angle ϕ . This stereospecificity is purely electronic in nature.
3. It correlates with other purely electronic quantities that are dependent on the same electronic transmission path, such as substituent effects on chemical shifts by electron-withdrawing or -donating groups. The electronic transmission path is most easily explored by the isotope shift, because substitution of an atom by a heavier one leads to the fewest complications compared with other methods of investigation such as replacement by atoms or groups of different electronegativity or size.

6 ISOTOPE EFFECTS ON SPIN-SPIN COUPLING

The indirect spin-spin coupling constant J is a useful index of the chemical bond, and isotope effects on it provide

information about the sensitivity of J to bond extension. Since the isotope effects on the isotropic average J can be determined more precisely than the individual J tensor components or the anisotropy, the isotope effects can be considered as *the* major source of experimental information for assessing the quality of ab initio theoretical calculations of indirect spin–spin coupling.

The working definitions of the isotope effects on J are as follows.⁴ $\Delta_s {}^n J(AB)[{}^{m'}/{}^m X]$ is the *secondary* isotope effect on the n -bond coupling constant between nuclei A and B due to the substitution of ${}^m X$ by the heavier isotope ${}^{m'} X$ somewhere in the molecule:

$$\Delta_s {}^n J(AB)[{}^{m'}/{}^m X] = |{}^n J(AB)|^* - |{}^n J(AB)| \quad (64)$$

$\Delta_p {}^n J(A^{2/1}H)$ is the *primary* isotope effect on the coupling constant between nuclei A and H due to the substitution of H by D, the coupled nuclei being separated by n bonds:

$$\Delta_p {}^n J(A^{2/1}H) = |{}^n J(AD)|^* \frac{\gamma_H}{\gamma_D} - |{}^n J(AH)| \quad (65)$$

where $\gamma_H/\gamma_D = 6.514\,398\,04(120)$. Of course, if we instead use the purely electronic quantities, namely, the reduced coupling constants

$${}^n K(AH) \equiv 4\pi^2 \frac{{}^n J(AH)}{h\gamma_A\gamma_H} \quad (66)$$

usually expressed in reduced units of $10^{19} \text{ J}^{-1} \text{ T}^2$, then the primary isotope effect is simply a difference:

$$\Delta_p {}^n K(A^{2/1}H) = |{}^n K(AD)|^* - |{}^n K(AH)| \quad (67)$$

Only the absolute values are compared, for practical reasons, since the absolute signs of spin–spin coupling constants are not always known. As in isotope shifts, the asterisk * denotes the heavier isotopomer. Where both secondary and primary isotope effects are observed, the primary isotope effect should be obtained from, for example, $J(\text{SnD})$ in SnH_2D^- and $J(\text{SnH})$ in SnH_3^- , rather than $J(\text{SnD})$ and $J(\text{SnH})$ in the same isotopomer SnH_2D^- . The latter difference includes both primary and secondary isotope effects.

Isotope effects on nuclear shielding are usually visually obvious in a high-resolution NMR spectrum, since the peaks of the isotopomer are shifted from the parent species. On the other hand, isotope effects on coupling constants are only observed as very slightly different multiplet splittings for each isotopomer (secondary isotope effects) or as a slightly smaller (usually) or larger $J(AD)$ than that expected from $J(AH)/6.514\,398\,04$ (primary isotope effects). Because of this factor of 6.514..., the isotope effects on J are less precisely determined than the isotope effects on shielding. According to these working definitions, a positive isotope effect on J means that the reduced coupling is larger in the deuterated species.

6.1 Observed General Trends in Isotope Effects on J

The general trends and their theoretical explanation have been presented by Jameson and Osten.⁴

1. The sign of the primary or secondary isotope effect on the coupling constant is not directly related to the absolute sign of the coupling constant. Whether it is related to the absolute sign of the reduced coupling constant is not yet established, since one-bond coupling isotope effects are presently available for positive reduced coupling constants only.
2. Primary isotope effects are negative or positive, the positive signs being found only in molecules involving one or more lone pairs of the coupled nuclei. For example, primary isotope effects are positive in H_2Se , in PH_3 , and in other 3-coordinate phosphorus, but negative in PH_4^+ and in 4- and 5-coordinate phosphorus. It is positive in SnH_3^- (one lone pair) and negative in SnH_4 and SnH_3^+ (no lone pairs).
3. Secondary isotope effects can have either sign, but are often negative. Positive signs have been observed where triple bonds are involved (as in $\text{HC}\equiv\text{CH}$ and $\text{HC}\equiv\text{N}$), but also in some of the same systems with positive primary isotope effects.
4. Secondary isotope effects are roughly additive upon substitution of several equivalent sites neighboring the coupled nuclei. For example, in the NH_4^+ ion, each D substitution decreases ${}^1J(^{14}\text{NH})$ by 0.05 ± 0.02 Hz, and in PH_3 , each D substitution decreases ${}^1J(\text{PH})$ by 2.5 Hz. Small deviations from additivity have been observed.
5. The magnitudes of isotope effects are small, the largest primary effect being about 10% of the coupling constant in SnH_3^- , so that only the effects of deuterium (and tritium) substitution, where the largest fractional changes in mass are involved, have been observed. Some of the larger primary isotope effects are +11.5 Hz for $\Delta_p {}^1J(\text{PH})$ in PH_3 and +10.5 Hz in SnH_3^- . Secondary isotope effects as large as -2.0 Hz per D [for ${}^1J(\text{SiF})$] and +3.0 Hz per D [for ${}^1J(\text{SnH})$] have been observed.
6. The magnitudes of the isotope effects are roughly proportional to the fractional change in mass, in the very few instances where effects of isotopic substitution of ${}^1\text{H}$ by ${}^2\text{H}$ and ${}^3\text{H}$ have been reported.

6.2 Rovibrational Averaging of J , the Leading Terms

Just as in isotope shifts, the isotope effect on J can be written in terms of products of electronic and dynamic factors as follows.⁶ For a diatomic molecule,

$$\begin{aligned} \langle J \rangle^* - \langle J \rangle &= \left(\frac{\partial J}{\partial r} \right)_e (\langle \Delta r \rangle^* - \langle \Delta r \rangle) \\ &+ \frac{1}{2} \left(\frac{\partial^2 J}{\partial r^2} \right)_e [\langle (\Delta r)^2 \rangle^* - \langle (\Delta r)^2 \rangle] + \dots \end{aligned} \quad (68)$$

The dynamic factors are the same as we have already discussed (and, indeed, the same for all rovibrational averaging of any molecular electronic properties). Only the electronic factors need be discussed here. Of course, γ of some nuclei are negative, so we really should compare derivatives of the reduced coupling such as $(\partial K/\partial r)_e$, etc., where

$$\left(\frac{\partial J}{\partial r} \right)_e = \frac{h\gamma_N\gamma_{N'}}{4\pi^2} \left(\frac{\partial K}{\partial r} \right)_e \quad (69)$$

One important difference between J and σ is that the latter is a one-center property whereas the former is a two-center

Table 10

	Experimental ¹⁵		Calculated	
	$K(\text{SnH})$ (reduced units)	$K(\text{SnD})$ (reduced units)	$K(\text{SnH})$ (reduced units)	$K(\text{SnD})$ (reduced units)
SnH_3^-	24.09 ± 0.01		24.09	
SnH_2D^-	24.76 ± 0.02	27.09 ± 0.14	24.76	27.08
SnHD_2^-	25.40 ± 0.03	27.72 ± 0.22	25.43	27.75
SnD_3^-		28.53 ± 0.43		28.42

property. In polyatomic molecules, there are usually several electronic factors of comparable size that contribute to the isotope effects on J . For polyatomic molecules, if 1J is most sensitive to the bond length, the one-bond shifts can also be written in the same way as for diatomic molecules, with the terms such as $(\partial J/\partial \alpha)_e(\langle \Delta \alpha \rangle^* - \langle \Delta \alpha \rangle) + \dots$ being less important. 2J and 3J , on the other hand, are very sensitive to bond and torsion angles.⁶²

Let us consider SnH_4 as an example rather than CH_4 , since fairly large isotope effects on SnH coupling have been observed. The types of terms that contribute to the vibrationally averaged spin–spin coupling are the same as those that contribute to the proton shielding in CH_4 as given in equation (51):

$$\langle K(\text{SnH}_1) \rangle = K_e + P_r \langle \Delta r_1 \rangle + P_s (\langle \Delta r_2 \rangle + \langle \Delta r_3 \rangle + \langle \Delta r_4 \rangle) + \text{terms in } P_{rr}, P_{ss}, P_{rs}, P_{st}, P_{\alpha}, \text{ etc.} \quad (70)$$

where the primary derivative is $P_r \equiv (\partial K(\text{SnH}_1)/\partial r_{\text{SnH}_1})_e$ and the secondary derivative is $P_s \equiv (\partial K(\text{SnH}_1)/\partial r_{\text{SnH}_2})_e$. If we let $d \equiv \langle \Delta r_{\text{SnH}} \rangle$ in SnH_4 and $d - \Delta \equiv \langle \Delta r_{\text{SnD}} \rangle$ in SnD_4 then $d \approx 1.780$ pm and $\Delta \approx 0.5161$ pm can be obtained for $r_e = 170$ pm using the method described in Section 3.1. K_e is the reduced coupling constant at the equilibrium molecular geometry. The leading terms are⁶

$$\text{SnH}_4: \quad \langle K(\text{SnH}) \rangle = K_e + (P_r + 3P_s)d + \dots \quad (71)$$

$$\text{SnH}_3\text{D}: \quad \langle K(\text{SnH}) \rangle = K_e + (P_r + 2P_s)d + P_s(d - \Delta) + \dots \quad (72)$$

$$\langle K(\text{SnD}) \rangle = K_e + P_r(d - \Delta) + 3P_s d + \dots \quad (73)$$

$$\text{SnH}_2\text{D}_2: \quad \langle K(\text{SnH}) \rangle = K_e + (P_r + P_s)d + 2P_s(d - \Delta) + \dots \quad (74)$$

$$\langle K(\text{SnD}) \rangle = K_e + (P_r + P_s)(d - \Delta) + 2P_s d + \dots \quad (75)$$

$$\text{SnHD}_3: \quad \langle K(\text{SnH}) \rangle = K_e + P_r d + 3P_s(d - \Delta) + \dots \quad (76)$$

$$\langle K(\text{SnD}) \rangle = K_e + (P_r + 2P_s)(d - \Delta) + P_s d + \dots \quad (77)$$

$$\text{SnD}_4: \quad \langle K(\text{SnH}) \rangle = K_e + (P_r + 3P_s)(d - \Delta) + \dots \quad (78)$$

From the above, we see that the primary isotope effect, the difference⁶³

$$\begin{aligned} \Delta_p {}^1K(\text{Sn}^{2/1}\text{H}) &= {}^1K(\text{SnD})|_{\text{SnH}_3\text{D}}^* - {}^1K(\text{SnH})|_{\text{SnH}_4} \\ &= (428.21 \pm 0.14) - (429.19 \pm 0.02) \\ &\approx -P_r \Delta \end{aligned} \quad (79)$$

leads to $P_r \approx 1.90$ reduced units pm^{-1} . The primary isotope effect may also be taken from any of the differences

$|^1K(\text{SnD})|_{\text{SnH}_2\text{D}_2} - |^1K(\text{SnH})|_{\text{SnH}_3\text{D}}$ or $|^1K(\text{SnD})|_{\text{SnHD}_3} - |^1K(\text{SnH})|_{\text{SnH}_2\text{D}_2}$ or $|^1K(\text{SnD})|_{\text{SnD}_4} - |^1K(\text{SnH})|_{\text{SnHD}_3}$, leading to an average value $P_r = (\partial K(\text{SnH}_1)/\partial r_{\text{SnH}_1})_e \approx 2.00$ reduced units pm^{-1} . Note that at this level of approximation, only the primary derivative P_r is involved in the primary isotope effect.

At the same time, the difference

$$\begin{aligned} \Delta_s {}^1K(\text{SnH})[^{1/2}\text{H}] &= |K(\text{SnH})|_{\text{SnH}_3\text{D}}^* - |K(\text{SnH})|_{\text{SnH}_4} \\ &= (428.81 \pm 0.02) - (429.19 \pm 0.02) \\ &\approx -P_s \Delta \end{aligned} \quad (80)$$

leads to $P_s \approx 0.74$ reduced units pm^{-1} . Since this secondary isotope effect may be taken from three other differences such as $|^1K(\text{SnH})|_{\text{SnH}_2\text{D}_2} - |^1K(\text{SnH})|_{\text{SnH}_3\text{D}}$, etc., we get an average value $P_s = (\partial K(\text{SnH}_1)/\partial r_{\text{SnH}_2})_e \approx 0.75$ reduced units pm^{-1} and $K_e = 421.63$ reduced units. The primary isotope effect involves largely the primary derivative of the coupling constant, and the secondary isotope effect on the coupling involves largely the (secondary) derivative of the coupling constant with respect to stretching a remote bond.

We can do the same analysis for the isotopomers of SnH_3^- , and we find that the values $P_r = -5.80$ reduced units pm^{-1} , $P_s = -1.30$ reduced units pm^{-1} , and $K_e = 39.04$ reduced units reproduce the experimental values reasonably well, as seen in Table 10.

The agreement with the six experimental numbers is very good. These quantities can be translated back to Hz pm^{-1} as in Table 11.

It is interesting that, although the magnitude of the SnH coupling constant is about one order of magnitude smaller in SnH_3^- than in SnH_4 , the sensitivity of the spin–spin coupling to bond extension is almost three times as great. The lone pair is generally known to be responsible for negative contributions to the reduced coupling, leading to a much smaller magnitude of the spin–spin coupling. Apparently, it is also the lone pair (on Sn in SnH_3^-) that is responsible for the greater sensitivity to bond extension. By similar procedures, the changes in the reduced coupling constant with extension of the bond, $(\partial K/\partial r)_e$, or of an adjacent bond, $(\partial K/\partial r')_e$, can be estimated in other systems such as SnH_3^+ , PH_4^+ , PH_3 , PH_2^- , and SeH_2 from experimental values of $J(\text{AH})$ and

Table 11

	SnH_4	SnH_3^-
$(\partial J(\text{SnH})/\partial r)_e$ (Hz pm^{-1})	−9.00	+26.00
$(\partial J(\text{SnH})/\partial r')_e$ (Hz pm^{-1})	−3.40	+5.80
$\langle J(\text{SnH}) \rangle - J_e$ (Hz)	−34.1	+67.3
J_e (Hz)	−1899.3	−175.8

$J(\text{AD})$ combined with values of the dynamic factor calculated by the methods described in Section 3.1. These values are compared with some published theoretical values in Table 12. Since all are expressed as γ -free reduced coupling constants, these are purely electronic quantities, which can be directly compared with each other in sign and magnitude. Theory has shown that the Fermi contact term is most sensitive to bond stretch.^{64,65} Thus, it is not surprising that the magnitudes of the empirical derivatives in Table 12 increase with increasing spin density at the nucleus, just as the reduced coupling constants are known to do. The secondary derivative is generally smaller than the primary derivative, and both usually have the same sign. The earlier prediction by Jameson and Osten⁴ that $(\partial K(\text{AH})/\partial r)_e$ will generally be negative when A has lone pairs but will be positive otherwise appears to be correct.

In summary, the electronic factor in the one-bond coupling constant $(\partial K(\text{AH})/\partial r_{\text{AH}})_e$ has been found to have the following attributes that explain the observed trends.

1. For A without lone pairs, it is positive; that is, the magnitude of the coupling increases as the bond becomes stretched.
2. It is largely dominated by the Fermi contact term, which is very sensitive to the distance between the two nuclei, much more so than the spin–dipolar and orbital contributions to coupling.
3. Probably because of the dominance of the Fermi contact term, it is larger for nucleus A having larger atomic number.
4. For A with lone pairs, this electronic factor is negative. It is known that lone pairs make negative contributions to the spin–spin coupling. The sign of this electronic factor confirms that the lone pair contributions are very sensitive to bond extension.
5. The secondary electronic factor $(\partial K(\text{AH})/\partial r_{\text{AX}})_e$ is generally 2–5 times smaller than the primary electronic factor, and is a measure of the sensitivity of the coupling across one bond to the lengthening of another bond involving one of the coupled atoms.

In summary, the dynamic factors and electronic factors in isotope effects on NMR parameters have been characterized. The theoretical model is general for any molecular electronic property.²⁶ The effects can be completely understood within

the context of the Born–Oppenheimer approximation. Complete calculations can be carried out for individual molecules within this theoretical framework. Where such calculations have been carried out, the agreement with experiment is good. Under conditions where the leading terms are dominant, the molecule-specific higher order terms can be neglected so as to find explanations for and make predictions of the sweeping generalities that have surfaced empirically in isotope effects on NMR parameters. The dynamic factor that has been derived by assuming dominance of the bond stretching successfully predicted the mass dependence of the isotope effects observed later. The empirical electronic factors deduced from this model are found to be consistent (in sign, in magnitude, and in correlations with various quantities such as net charge, presence or absence of lone pairs, bond order, etc.) with the theoretical electronic factors obtained by ab initio calculations.

1 INTRODUCTION

By the late 1950s, all of the physics important to high-resolution solution NMR seemed to have been identified. The basic interactions of chemical shift and scalar or J couplings, as well as the dynamics leading to spin relaxation and chemical exchange, were understood—at least in principle. It seemed that all of the relevant terms in the Hamiltonian that applied to NMR in isotropic solutions were known. Advances in NMR theory focused on the details of dealing with complex spin systems and their manipulation by pulse trains, or how the spins reflected molecular dynamics, as exemplified in this Encyclopedia. This article deals with the recent recognition of an additional term in the solution NMR Hamiltonian, namely, that for nuclear–nuclear exchange coupling, and the dramatic effects it can have on solution NMR spectra. The purpose is to provide the reader with as intuitive and physical a picture of this purely quantum mechanical effect as possible. More rigorous treatments of the details of the underlying physics may be found in the references.

2 EXPERIMENTAL OBSERVATIONS

The discovery of nuclear–nuclear exchange couplings or quantum exchange couplings in solution NMR spectroscopy^{1–3} grew out of NMR studies of transition metal polyhydrides in the 1980s. Kubas at Los Alamos National Laboratory had discovered a class of transition metal complexes that bind H_2 as an intact ligand, rather than oxidatively adding the H_2 to the metal center.⁴ This prompted a great deal of activity among inorganic chemists in the synthesis of new hydride and dihydrogen complexes, as well as the reinvestigation of many previously known systems. At the time, the synthetic chemists also postulated that species such as H_3^+ might also be stabilized as ligands in transition metal complexes. Solution NMR spectroscopy of 1H was usually the structural method of choice in these investigations, and the classic signature of an H_2 complex became a measurable value for $^1J(^1H, ^2D)$ in the HD isotopomer, usually of the order of 20–35 Hz. It was widely assumed that a large value of $^1J(^1H, ^1H)$ would be found in any H_3 complex.

In the late 1980s, Heinekey at Yale and Chaudret at Toulouse independently^{5,6} made some somewhat startling observations

in the 1H NMR of several transition metal trihydrides. In these systems, the spectra indicated that $^1J(^1H, ^1H)$ could be over 200 Hz. Since the coupling in molecular H_2 itself is only 280 Hz as inferred from the NMR of HD, these large values for 1J were at first glance evidence for the putative H_3^+ complexes. However, it soon became clear that these systems were not to be explained so simply. During the next few years, Heinekey carried out a set of classic experiments that formed the basis on which it is now accepted that these splittings are exchange couplings.

One of the first indications that the observed splittings were not due to the usual Fermi-contact mediated scalar coupling mechanism was their extreme sensitivity to temperature. Early on, the apparent J couplings seemed to be field-dependent. However, careful experiments by Heinekey showed that this apparent B_0 dependence arose from slight variations in the probe temperature on different instruments. The splittings in fact did not depend upon field, but instead were hypersensitive to temperature. Many alternate models were considered for explaining these observations at the time. Some invoked chemical equilibria involving an unusual thermally accessible state that would have unprecedentedly large J couplings. Several tunneling-type mechanisms were also considered, but these seemed difficult to resolve with the observation of these splittings in fluid media at close to ambient temperatures. (For a review of previous experimental observations, other models eliminated, and pertinent references, see Zilm and Miller.⁷) Heinekey then carried out some very important experiments employing 2D substitution. The resulting pattern of isotope shifts and the isotopic variations on the apparent values of $^1J(^1H, ^1H)$ in the remaining protons ruled out any sensible model involving chemical equilibrium.² Unfortunately, the spectra of the partially deuterated isotopomers themselves did not provide convincing evidence for the involvement of tunneling. While no $^1J(^1H, ^2D)$ couplings were observed, this observation could be explained just as convincingly by self-decoupling due to the rapid 2D relaxation in concert with chemical exchange as by a tunneling mechanism. The key experiment to perform became clear. The NMR of a partially tritiated isotopomer would have none of the complications encountered with deuterium. Given the difficulties in handling radioactive samples, this experiment was more than difficult to perform. The results were well worth Heinekey's efforts: a coupling that started as over 500 Hz in a perprotio molecule was reduced to a $^1J(^1H, ^3T)$ of less than 30 Hz at the same temperature.¹ This was the first conclusive evidence obtained in favor of the exchange coupling mechanism for these large temperature dependent couplings. The initial report¹ of this result and a theoretical framework for quantitatively accounting for these couplings and their temperature dependence was soon published. Simultaneously with this report, Jones and Weitekamp⁸ also proposed an exchange coupling mechanism in these systems, which utilized symmetry arguments, but with no additional experimental data.

3 THEORY

Exchange interactions among electrons are familiar to any student of solid state physics or quantum chemistry. They are central to the quantum mechanical description of bonding in

molecules and the mechanism of phenomena such as high-temperature superconductivity. The appearance of $JI_1 \cdot I_2$ type couplings in ESR spectra of triplet biradicals is a well-known spectroscopic manifestation of the electron–electron exchange interaction. For nuclei, quantum mechanical exchange interactions are less familiar, and until recently they were not known to affect high-resolution magnetic resonance spectra in any manner. (For references on quantum exchange in solid ^3He and in related electronic structure problems, see Zilm and Miller.⁷) The best-known example of heavy particle quantum exchange is in solid ^3He . In this system, diffusion rates and other properties are known in large part to be determined by ^3He – ^3He exchange interactions. NMR spectra of tunneling methyl groups at low temperature also display features related to rotational tunnel splittings, but these have not usually been considered as manifestations of an exchange interaction per se. Given that quantum effects such as these have typically been considered as purely low-temperature phenomena, it is not surprising that quantum exchange involving nuclei has not until recently been recognized as having any role in solution NMR spectroscopy.

Any theory accounting for quantum exchange must consider the total wavefunctions for the nuclei being observed, spanning both spin and spatial coordinates. In this respect, quantum exchange is quite distinct from the other terms in the NMR Hamiltonian. A typical NMR interaction can usually be written as a product of a spin operator and an interaction constant or tensor, which is an expectation value of the rest of the system Hamiltonian over all coordinates except spin. In quantum exchange, however, the spin coordinate and the spatial coordinate are correlated, and such a separation is not possible. To illustrate this, we shall consider a simple two-spin system where the spins occupy chemically inequivalent sites.

3.1 Molecular Dynamics

To understand quantum exchange in the context of NMR spectroscopy, we must first consider the quantum mechanics governing the Cartesian displacements of the NMR active nuclei, i.e., their orbital wavefunctions, and then see how this is coupled to their spin coordinates, i.e., the spin functions. For a start, we shall consider a simple two-particle quantum mechanics problem that is often somewhat misunderstood. Although our treatment will be quite similar to a number of familiar problems in tunneling (see, e.g., Atkins⁹), we should like to emphasize now that quantum exchange does not in fact imply that tunneling motions occur. This point will be clarified in the following discussion.

The molecular systems in which quantum exchange has been observed by NMR all are of the form (1)

where the other ligands collectively denoted by L_3 are typically another hydride, a cyclopentadienyl, and a phosphine. Single crystal neutron diffraction studies³ indicate that the hydrides are typical terminal hydrides having a single bond to the central transition metal atom M. Although the M–H linkages are

significantly more ‘floppy’ than C–H bonds, these hydrides are basically localized at their binding sites. To a very good approximation, the potential well that each of these hydrides experiences can be approximated by the harmonic oscillator potential as depicted in Figure 1(a).

A complete quantum mechanical treatment of the pair of hydrides under consideration would involve a six-dimensional potential energy surface describing the energy of all configurations of the two hydrides as they are moved relative to each other and to the metal center. As long as the hydrides remain outside each other’s van der Waals radii, the potential experienced by either is still roughly harmonic. If the hydrides do not have any appreciable interaction with one another, the problem reduces to that of two uncoupled harmonic oscillators.⁷

As a simple model for this system, consider two hydrides bound to a surface, each in locally harmonic single particle potentials, (2) and (3).

If the interaction between the two protons is sufficiently weak, their displacements are approximately harmonic except for the symmetric displacement towards one another. In this instance, each hydride feels a repulsive force, which rises rapidly as they near one another. The hydrides are also attracted to the potential minimum at the other binding site. It is the displacement of the hydrides along this type of coordinate that we shall focus upon.

A good model potential for displacements along this exchange coordinate is a double well potential such as that in Figure 1(b). Movement along this coordinate exchanges the two hydrides between the two wells. The reaction coordinate is a two-particle potential, and is necessarily somewhat complicated. If the hydrides simply each moved along the y axis towards one another, there would be an essentially infinite barrier separating the two configurations. The model we want to consider instead takes the coordinate to be a minimum energy type of path along which exchange is possible. At the barrier the two particles must move out of each other’s way along a path that takes them out of the (y, z) plane.

It is worthwhile to note what is, and what is not, important in the choice of this potential energy curve. The double well model is only one approach to connecting the two different possible ground state configurations of the hydrides. Displacement on a periodic rotational coordinate would also produce the type of effects to be discussed.¹⁰ The required features are only that the potential has two wells representing two distinct configurations and that there be a finite barrier separating them.

Having reduced the two-particle problem to a single internal reaction coordinate in a double well makes the problem fairly simple. We shall only consider the vibrational ground state in this potential, since we know that the hydrides are basically bound fairly tightly to their binding sites. This places them in one of the two configurations representing the double well minima. Near the bottom of either well, the potential is close to harmonic, and a good approximate two-particle ground state

Figure 1 (a) Depiction of two harmonic potentials at two different sites, with vibrational ground state wavefunctions. This is a reasonable description of two largely uncoupled M–H vibrators in a transition metal hydride. The coordinates are the displacements of the individual hydrides. (b) A model two-particle potential describing the change in potential energy as the two hydrides in the two sites shown in (a) are exchanged between the two sites. The coordinate is the reaction coordinate along which the exchange takes place. The wavefunctions shown are two-particle wavefunctions for the two degenerate configurations

wavefunction would be a Gaussian centered in either of the two wells. We define $\psi(L)$ as the configuration where the protons 1 and 2 were at sites A and B, respectively. This configuration can be written as a product of one-particle wavefunctions, i.e., $A(1)B(2)$, where $A(1)$ and $B(2)$ are the Gaussians representing the one-particle ground state vibrational wavefunctions in the single particle potentials representing the two binding sites. The other side of the double well would then be represented by the two-particle wavefunction $\psi(R)=A(2)B(1)$ [see Figure 1(b)].

It is tempting to apply what we know about the quantum mechanics of a single particle in a double well directly to this two-particle problem, since the mathematical formulation is now the same at this point (see, e.g., Atkins⁹). Because the wells are a finite distance apart, the wavefunctions for the two ground state basis configurations we have chosen overlap each well. This produces an off-diagonal element in the matrix for the system Hamiltonian $\hat{\mathcal{H}}_L$ that includes the interaction of the particles with both wells and each other. To get the best possible description of the ground state within this restricted basis set, we must diagonalize this matrix. If

Figure 2 Model double well exchange potential showing the two lowest energy eigenfunctions ψ_+ and ψ_- . The energies of these two states are split by $2J$ symmetrically about the energy of the two degenerate localized basis states

the two sides of the double well have the same depth, the basis states are degenerate. No matter how small the off-diagonal term, the two basis set wavefunctions will be mixed. As every student of quantum mechanics knows, in the single particle case the symmetric and antisymmetric combinations of the two Gaussians are then good approximations to the proper wavefunctions. The eigenenergies of the two eigenstates $\psi_{\pm} = \frac{1}{2}[\psi(L) \pm \psi(R)]$ for the symmetrical potential are $E_{\pm} = \bar{E} \pm J$ (see Figure 2). $\bar{E}$ is the unperturbed energy of either of the degenerate configurations given by

$$\int \int [A(1)B(2)]^* \hat{\mathcal{H}}_L A(1)B(2) d\tau_1 d\tau_2 \quad (1)$$

and J is the value of the off-diagonal matrix element

$$\int \int [A(1)B(2)]^* \hat{\mathcal{H}}_L A(2)B(1) d\tau_1 d\tau_2 \quad (2)$$

In the case of a single particle in the double well, the energy difference $2J$ is a tunnel splitting. The wavefunctions indicate that the particle is equally likely to be in either well. This is interpreted to mean that the particle is ‘delocalized’ over both sides of the potential. If a localized state is prepared by a superposition of ψ_+ and ψ_- , it will evolve in time according to the usual rules of time-dependent quantum mechanics. The picture that emerges is one of the maximum in the probability density oscillating between the two wells at a frequency $2J/\hbar$. One usually describes the particle as coherently tunneling from one well to the other at this rate. On the other hand, when the two wells are of differing depths, the particle quickly becomes localized. As long as the difference in the energies of the two states $\psi(L)$ and $\psi(R)$ is larger than the off-diagonal term J , these remain good states to first order in the perturbation treatment.

The mapping of the two-particle case onto this reduced one-particle description contains some subtleties. If the two

sites are energetically the same, i.e. the one-particle potentials at the two binding sites are identical, the configurations $A(1)B(2)$ and $A(2)B(1)$ will clearly have the same energies. The degeneracy will again be lifted by any finite matrix element connecting the functions $A(1)B(2)$ and $A(2)B(1)$, and there will be two states separated by a tunnel splitting. In the molecules we are considering, however, the hydrides are chemically inequivalent. This means that the local one-particle potentials are different, if only slightly so on a cm^{-1} scale. However, this does not necessarily break the symmetry of the two-particle potential along the exchange coordinate. If the two particles are identical, the basis configurations $A(1)B(2)$ and $A(2)B(1)$ representing $\psi(L)$ and $\psi(R)$ will still have the same energies. Exchange of identical particles can then be described by a mirror-symmetric two-particle potential in the exchange coordinate. If the hydrides are not identical (e.g., a proton and a triton), this symmetry will be broken, since the two basis configurations will have different energies. The eigenstates will then be localized, and no tunneling will occur. In this case of two distinguishable particles, the two sites would have to be identical for the exchange potential to remain symmetric.

The appearance of a potential for particle exchange with mirror symmetry is then a prerequisite for exchange splittings to appear in the energy level diagram for this two-particle system. Many familiar systems have this type of symmetry, but not all can display quantum exchange. For example, consider the umbrella mode of ammonia, or the chair-to-chair inversion of cyclohexane. In the gas phase, both displacements can be described by mirror-symmetric double wells. Placing these molecules into a condensed phase, however, breaks this symmetry. When either molecule inverts, it moves from one region of space to another. The presence of an anisotropic solvent shell around each site gives the configurations distinct energies. This is not the case for the transition metal polyhydrides we are considering, or other systems such as rotating methyl groups. In the transition metal hydrides, the configuration before and after the exchange of two hydrides occupies the same region of space. Rotation of a methyl group by 120° likewise results in a new configuration that occupies the same space as before the rotation. These displacements are then always instantaneously described by mirror-symmetric potentials, and thus will have exchange-type splittings appearing in their energy level structure. It should be emphasized that whether particles are identical or not depends only on the nature of the particles and not on their location in the molecule or lattice. However, whether a molecular rearrangement that exchanges identical particles is a truly degenerate rearrangement energetically depends on the relation of the molecule to the lattice at the beginning and the end of the rearrangement.

The above treatment of the two-particle exchange problem as a single pseudoparticle in a double well is only partially correct. This is because the two-particle wavefunctions have additional constraints. One must remember that the spatial portion of a wavefunction describes the probability of a particle's location. When several particles are described by a single wavefunction, the probabilities can only be ascribed individually to particles that are distinguishable. For indistinguishable particles, the identity (e.g., particle number) is irrelevant.¹¹ The wavefunction for a pair of identical particles can then only give the probability of finding a particle

of that type at any position. It cannot tell us the probability for finding a particular particle there.

Our interpretation of $\psi_{\pm}$ in the one- and two-particle cases, then, is somewhat different. For the single particle in the double well, the equal probability amplitudes on the left and right sides is taken as an indication that the particle is 'delocalized' over both sides. This notion is reinforced by the time-dependent behavior of a single particle in this potential if the initial state is localized as just discussed. On the other hand, the two-particle wavefunctions $\psi_{\pm}$ do not imply delocalization of the two particles, or of the configuration. These functions now simply state that the system is most likely in a configuration with one particle on the left and one on the right, but the identity of the configuration is indeterminate. We may not ask about the location of individual particles, since they are identical, and as such their labels are simply irrelevant. Thus, we see in the two-particle case that the indeterminacy as to which particle is on the left or on the right has replaced the delocalization that arises in the one-particle problem.

This statistical interpretation of the two-particle wavefunctions requires that any relabeling of the particle identities must leave the probability densities unchanged. Thus, the wavefunction must be the same, or at most change sign, when the particle labels are permuted. In accord with the well-known symmetrization postulate, wavefunctions for identical bosons are symmetric or remain the same, while those for identical fermions are antisymmetric or change sign, under particle label exchange. With this in mind, we return to the problem of two particles in the double well. Consider the case where the particles are of zero spin and are therefore bosons. The function ψ_+ has the proper symmetry, while ψ_- does not. The ground state can then only exist as ψ_+ , since ψ_- is an unacceptable wavefunction. The consequence of this is that a 'localized' state cannot be constructed by combining ψ_+ and ψ_- . The picture we arrived at in the one-particle state of an initially localized state periodically moving between the two wells is then inappropriate. The system can only remain in the ground state ψ_+ . This is most easily interpreted as the system being localized in one of the two possible indistinguishable configurations.

3.2 Including the Spin Coordinate

When the spin functions are included in the two-particle problem, the symmetry of the total wavefunction including spin must be considered. One place to start is to write the individual spatial and spin functions as separate symmetrized sets. For a pair of spin- $\frac{1}{2}$ nuclei the symmetrized functions are the symmetric triplet functions T_0 , T_{-1} , T_{+1} , and the antisymmetric singlet spin function S_0 . The total wavefunction for identical fermions must be antisymmetric with respect to exchange, and therefore ψ_+S_0 , ψ_-T_0 , ψ_-T_{-1} , and ψ_-T_{+1} are the only acceptable combinations. Now that spin has been introduced, the system can have an energy of either $E + J$ or $E - J$, depending upon the spin state of the nuclei. Any additional small interaction of the magnetic field would not be expected to change the situation with respect to the energy associated with the orbital or lattice terms of the Hamiltonian. On the other hand, magnetic interactions will mix the singlet and triplet spin manifolds. Any spin flip that occurs must also make up any difference in lattice energy accompanying the transition. The appearance of the exchange energy in an

NMR transition is then a consequence of the correlation of the spin states with the orbital energies associated with the displacements of the NMR active nuclei.

In general, the above type of prescription for determining properly symmetrized total spin + spatial wavefunctions is cumbersome. The resulting functions can be recast in a more physical and convenient basis, which we call the site spin basis.¹¹ Rather than deriving the site spin basis, we shall develop it directly from some basic symmetry considerations. Let us start by considering a pair of protons in chemically equivalent sites that comprise an AX spin system. Normally we ignore the complications brought on by the coordinate or orbital part of the wavefunction, and simply write the spin eigenfunctions as $|+ +\rangle$, $|+ -\rangle$, $|- +\rangle$, and $|- -\rangle$, where the labels refer to m_S for particles 1 and 2 in that order. These two-particle product basis spin functions themselves, however, do not have the proper symmetry with respect to particle exchange, i.e., $|+ -\rangle \neq \pm |- +\rangle$. This at first sight seems perplexing, since every NMR spectroscopist knows that these wavefunctions are what are always used for an AX spin system. The answer is that in actuality the spin labels do not refer to the particle identities. Instead, the functions are of the form $|m_S(A), m_S(B)\rangle$, i.e., the labels are according to the site identity, not the particle numbers. The function $|+ -\rangle$ says the particle in site A is in the + state, and the particle in site B is in the - state. What the function does not tell us is which particle is in which site. Therefore, the spin functions labeled according to the m_S in each site are automatically symmetric with respect to particle exchange. To differentiate the product basis labeled according to sites, we shall write these kets as $|+ -'\rangle$.

In using this site labeling convention, we must also relabel our spin Hamiltonian.¹¹ For instance, the Zeeman plus chemical shift term in frequency units for two spins would be written as

$$\hat{\mathcal{H}}_{cs} = -\nu_A \hat{I}_{zA} - \nu_B \hat{I}_{zB} \quad (3)$$

The resonance frequencies and spin operators are thus identified with the molecular site instead of a particle number. In most instances, this is in fact how NMR problems are typically handled, even though one may have the impression that one is using particle labels instead of site labels.

The overall symmetry of the total site spin basis function $\psi_{\text{site}} = \psi_{\text{orbital}} \psi_{\text{spin}}$ is then determined solely by the symmetry of the orbital wavefunction. For this pair of spin- $\frac{1}{2}$ nuclei, ψ_{orbital} must always be the antisymmetric function ψ_- , since ψ_{spin} is always symmetric with this site labeling convention. The total wavefunction for the $|+ -'\rangle$ spin state is then $\frac{1}{\sqrt{2}}[A(1)B(2) - A(2)B(1)]|+ -'\rangle$ (the normalization is only approximate, since we have ignored the small overlap term). As a shorthand, these site spin basis functions will be written as $|m_S(A), m_S(B)\rangle$, dropping the prime notation to imply the inclusion of the orbital portion. Remember that the labeling of the spin portion is according to site A and B, not particle 1 and 2, in these functions with the '[]' notation. In order to calculate a spectrum, it is instructive first to explicitly calculate a few matrix elements. We shall use the sum of the coordinate Hamiltonian for the particles, $\hat{\mathcal{H}}_L$, and $\hat{\mathcal{H}}_{cs}$ as an example.

First consider $\langle + - | \hat{\mathcal{H}}_{cs} | + - \rangle$. Using the site labeling convention, this is evaluated as $\frac{1}{2}(\nu_B - \nu_A)$ in the usual fashion. The integral over the particle coordinates is unity, since the

orbital function is normalized. To calculate $\langle - | \hat{\mathcal{H}}_L | + - \rangle$, we must expand $|+ -\rangle$ in terms of functions with particle labels:

$$|+ -\rangle = \frac{1}{2}[A(1)B(2)|+ -\rangle - A(2)B(1)|+ -\rangle] \quad (4)$$

Since the spins have particle number designations on the right-hand side, the + and - labels have been arranged to keep the + spin in the A site and the - spin in the B site. The quantity $\langle + - | \hat{\mathcal{H}}_L | + - \rangle$ can be written as a sum of products of integrals over spin and space separately:

$$\begin{aligned} \langle + - | \hat{\mathcal{H}}_L | + - \rangle &= \frac{1}{2} \langle + - | + - \rangle \int \int [A(1)B(2)]^* \hat{\mathcal{H}}_L A(1)B(2) d\tau_1 d\tau_2 \\ &\quad + \frac{1}{2} \langle - + | - + \rangle \int \int [A(2)B(1)]^* \hat{\mathcal{H}}_L A(2)B(1) d\tau_1 d\tau_2 \\ &\quad - \frac{1}{2} \langle - + | + - \rangle \int \int [A(2)B(1)]^* \hat{\mathcal{H}}_L A(1)B(2) d\tau_1 d\tau_2 \\ &\quad - \frac{1}{2} \langle + - | - + \rangle \int \int [A(1)B(2)]^* \hat{\mathcal{H}}_L A(2)B(1) d\tau_1 d\tau_2 \end{aligned} \quad (5)$$

Note again that the spin labels on the left refer to sites A and B, while those on the right refer to particle numbers 1 and 2. The first two integrals each give $\frac{1}{2}E$, and the last two are zero because of the vanishing integral over the spin coordinate. The net value of the element $\langle + - | \hat{\mathcal{H}}_L | + - \rangle$ is then the lattice energy E . Now consider the element $\langle - + | \hat{\mathcal{H}}_L | + - \rangle$. In a similar fashion, the integral can be expanded as

$$\begin{aligned} \langle - + | \hat{\mathcal{H}}_L | + - \rangle &= \frac{1}{2} \langle - + | + - \rangle \int \int [A(1)B(2)]^* \hat{\mathcal{H}}_L A(1)B(2) d\tau_1 d\tau_2 \\ &\quad + \frac{1}{2} \langle + - | - + \rangle \int \int [A(2)B(1)]^* \hat{\mathcal{H}}_L A(2)B(1) d\tau_1 d\tau_2 \\ &\quad - \frac{1}{2} \langle + - | + - \rangle \int \int [A(2)B(1)]^* \hat{\mathcal{H}}_L A(1)B(2) d\tau_1 d\tau_2 \\ &\quad - \frac{1}{2} \langle - + | - + \rangle \int \int [A(1)B(2)]^* \hat{\mathcal{H}}_L A(2)B(1) d\tau_1 d\tau_2 \end{aligned} \quad (6)$$

In this case, the first two integrals are zero, and the second pair give contributions of $-\frac{1}{2}J$ for a total value of $-J$.

The reader may already see that these matrix elements can be evaluated on inspection following a few simple rules. When dealing with the NMR or spin Hamiltonian, we proceed as normally, using spin operators, interaction coefficients, and spin functions labeled according to site. The coordinate part seems trickier, but can be simply treated as a permutation operator over the spin. For a term $\langle ij | \hat{\mathcal{H}}_L | kl \rangle$, a value of E is returned if $i = k$ and $j = l$. If $i = l$ and $j = k$, a contribution of $-J$ is obtained. The additional terms that the exchange interaction brings to the NMR Hamiltonian can then be recognized as having the same form as the classical exchange matrix familiar to students of dynamic NMR lineshape analysis.

Table 1 Hamiltonian Matrix in the Site Spin Basis for a Simple AX Spin System

	$ + +\rangle$	$ + -\rangle$	$ - +\rangle$	$ - -\rangle$
$\langle ++ $	$-\frac{1}{2}\nu_A - \frac{1}{2}\nu_B + E - J$	0	0	0
$\langle +- $	0	$-\frac{1}{2}\nu_A + \frac{1}{2}\nu_B + E$	$-J$	0
$\langle -+ $	0	$-J$	$+\frac{1}{2}\nu_A - \frac{1}{2}\nu_B + E$	0
$\langle -- $	0	0	0	$+\frac{1}{2}\nu_A + \frac{1}{2}\nu_B + E - J$

For our simple AX spin system, the full Hamiltonian matrix in the site spin basis can then be written on inspection as in Table 1. Since the orbital energy E only adds to the diagonal, it just represents a shift of the energy scale and can arbitrarily be set to zero. If the chemical shift difference $|\nu_A - \nu_B| \gg |J|$ then the off-diagonal terms will be truncated, and the NMR transitions will give two doublets centered at ν_A and ν_B with splittings of $-2J$. This Hamiltonian then gives the same spectrum as that for an AX spin system with an effective J coupling of $-2J$. Since the matrix element that J represents is inherently negative, the apparent coupling in the spectrum is positive. For spin- $\frac{1}{2}$ nuclei, it can be shown that any pairwise exchange interaction gives rise to a term that behaves just as if there were a scalar coupling $-2J$ between those two sites. Higher-spin systems, however, cannot be described by such a simple effective spin Hamiltonian.¹¹

One could incorrectly infer from the energy level structure of this simple example that the identity of the particles can somehow be made known by the fact that they experience different chemical shifts at the two different sites. A question that might be asked is how often the spins can change places by tunneling. The answer turns out to be that one cannot tell. The probability that a spin in site A has exchanged with a spin in site B becomes a maximum when their spin quantum numbers are identical. In other words, the spins can tunnel when one cannot tell them apart, even by their spin. Therefore, the most straightforward interpretation is that the spins remain localized, but which spin is localized where is something that cannot be known, since the particles are indistinguishable.

The advantage of the site spin basis approach to treating exchange coupling in NMR spectroscopy is that it is very easily extended to more complicated permutations or exchanges of spins, and is easily applied to problems involving nuclei of arbitrarily large I . The general form of the exchange Hamiltonian in the site spin basis can be shown¹¹ to be

$$\hat{H}_{\text{ex}} = \sum_i \xi^{p(i)} J_i \hat{P}_i(k, l, m, \dots) \quad (7)$$

where $\xi = e^{2\pi i l}$ and I is the spin quantum number of the nucleus in question. The permutation of the spins among the sites $k, l, m, \dots$ is represented by the operator $\hat{P}_i(k, l, m, \dots)$, which acts on the spin labels within the site spin basis functions. Each site spin basis function has the same orbital function implied. For fermions, this is formed using a Slater determinant for the orbital states for each site. If the nuclei are bosons, an antideterminant is used instead. The exchange matrix element is given by J_i . It is calculated by taking the matrix element of $\hat{H}_L$ between an orbital state for one configuration and that of the configuration resulting from the permutation. For example, consider a three-site problem (e.g., a methyl group). A starting configuration would be

$A(1)B(2)C(3)$. If the three particles are subjected to a cyclic permutation, this state would become $A(3)B(1)C(2)$. The value of J_c would be

$$J_c = \iiint [A(1)B(2)C(3)]^* \hat{H}_L A(3)B(1)C(2) d\tau_1 d\tau_2 d\tau_3 \quad (8)$$

Different permutations have different parities. For bosons, this is irrelevant. However, for fermions, permutations of even parity produce negative elements, and those of odd parity give positive exchange integrals. This is handled by the $\xi^{p(i)}$ term. If the nuclei are fermions with spin $I = n + \frac{1}{2}$ then $\xi = -1$. If they are bosons then $\xi = +1$. For fermions, a single pairwise permutation has odd parity, and $p(i) = 1$, which produces a negative sign for the exchange matrix element. On the other hand, a permutation that can be written as the product of two pairwise permutations has even parity, and $p(i) = 2$. These permutations give positive exchange coupling elements in the Hamiltonian matrix. One can show by straightforward but tedious calculations that the results of this prescription are to reproduce the matrix elements that would be obtained by expanding the site spin basis functions as products of properly symmetrized orbital functions and spin functions with particle labels, and performing the integration explicitly.

In practice, one simply associates a different J value with each particular topological rearrangement or permutation of the nuclei between the different locations in a molecule. High barrier permutations give low J values, and facile permutations give larger ones. The states that are connected are those where the permutation operation shuffles the spin labels so that they match those of the state to which it is coupled. The procedure is exactly the same as filling an exchange matrix for a classical chemical exchange lineshape problem. The signs of the elements are determined by whether the spins are fermions or bosons, and whether the permutation has even or odd parity. These elements are added to the rest of the standard NMR Hamiltonian, and the spectrum is determined by finding the eigenstates and determining the transition moments in the usual fashion.

A convenient starting point for computer simulation of exchange-coupled spectra in the presence of chemical exchange is to start with any of the many programs for dynamic NMR lineshape simulation. One simply duplicates the code for calculating the elements of the classical exchange matrix, and uses it to add exchange coupling elements to the Hamiltonian matrix. In this manner, we have been able to computer-simulate exchange-coupled NMR spectra for systems of up to four chemically exchanging protons or deuterons.

3.3 Temperature Dependence

Our main purpose so far has been to provide a physical picture of how exchange interactions produce splittings in

NMR spectra. The theory accounts for the disappearance of exchange couplings between different isotopes of the same element, for the persistence at ambient temperatures of an effect that is similar to tunneling, and for the different spectral patterns that are observed for spin- $\frac{1}{2}$ and spin-1 systems (see below). Accounting for the size of these splittings and their temperature dependence is another matter. Several models have been proposed, and probably all are correct to some extent. A definitive calculation of the exchange coupling would require an accurate $3N$ -dimensional potential energy surface for N identical nuclei. This is at present out of reach, so the models are either approximate analytical or computational attempts to focus on key features of the exchange process.

The model we have favored most is based on a treatment of exchange in solid ^3He by Landesmann.^{2,7} Landesmann has analytically calculated the ground state exchange splitting for two atoms in harmonic wells and repelled by a hard sphere potential. To account for the temperature dependence, thermal excitations that place the molecules in higher vibrational states are involved. Since these vibrationally excited states are more delocalized, there is more overlap of the individual particles with the neighboring sites, and the size of J goes up with vibrational quantum number. In the double well description, the splittings of the higher states increase exponentially as one moves beyond the ground state. In solution, the vibrational states are short-lived, and the NMR experiment measures a Boltzmann population weighted average of the splittings over the vibrational ladder. The spin state is conserved in these transitions, and the sign of J remains the same; therefore, the weighted average of J increases with temperature. We have shown that the sum over vibrational states can be effectively accomplished by first calculating a Boltzmann population weighted overlap function.⁷ This can be shown to be approximated by a Gaussian of increasing width with increasing temperature. As Landesmann's ground state calculation used a Gaussian basis set, this result can then be applied to the averaged splitting as a function of temperature also. The final expression obtained is

$$J(T) = \frac{-3\hbar a}{8\pi m \delta(T)^3} \sqrt{\frac{3}{\pi}} \exp\left[-\frac{3}{4} \frac{a^2 + \lambda^2}{\delta(T)^2}\right] \quad (9a)$$

where

$$\delta(T)^2 = \frac{3h}{4\pi m \nu} \coth\left(\frac{h\nu}{2kT}\right) \quad (9b)$$

Here a is the inter-hydride equilibrium distance, λ is a hard sphere radius (usually taken as 10 nm), ν is the bending frequency of the M–H bonds, and m is the proton mass. When deuterium or tritium is involved, the mass and bending frequency are adjusted accordingly.

Equation (9a) can be used to fit J versus T data, and both a and ν determined. The values found in a large number of fits are quite close to the distances a found by single crystal neutron diffraction and the few ν bending frequencies that have been measured.² For systems with very large ^1H – ^1H exchange interactions, this equation has correctly predicted the size of the ^2D – ^2D exchange couplings when they can be measured. This equation also explains why exchange couplings are not observed in organic molecules. The exchange coupling decreases about two orders of magnitude for every 100 cm^{-1}

increase in ν . Since C–H bends are of the order of 600 cm^{-1} higher than M–H bends, the exchange couplings in organic systems are about 10^{12} smaller and thus unobservable.

Jones and Weitekamp have developed a similar model using numerical diagonalization of model double well potentials.¹² The behavior of J versus T is calculated by a sum over the thermally populated states. One difficulty with this approach is making a connection between the model reaction coordinate and the molecular structure. Harris and co-workers¹³ have studied exchange using muffin-tin-type potentials. They are also able to account for the observed data, and have offered some insight into the types of reaction coordinates that may play an important role.

Limbach¹⁰ has proposed an alternative model to these that is most different in the assumed exchange coordinate. This is a rotational model that produces an exchange splitting from a periodic exchange potential. In the rotational tunneling problem, the tunnel splittings alternate in sign with increasing rotational quantum number. One might then expect that the exchange coupling would have to decrease with temperature in this model instead of increasing as is observed. To circumvent this problem, Limbach proposes that in the ground state the hydrides have no appreciable rotational tunnel splitting. Thermal excitations then allow the system to access a state that is a nascent H_2 complex. The H_2 ligand in this state has a substantial tunnel splitting, which produces the appearance of the exchange coupling. The temperature dependence arises from the thermal population of essentially just the lowest rotational state of the H_2 complex. Such a model can also be used to fit all of the experimental data collected on perprotio systems to date. The main difficulty with this model is rationalizing the existence of an H_2 complex that must lie only 4 – 8 kJ mol^{-1} above the ground state trihydride structure. In addition, the barrier to rotation of the H_2 ligand in the thermally excited state must be well over 40 kJ mol^{-1} to properly account for the apparent tunnel splitting in the lowest rotational state of this nascent H_2 complex.

Differentiation of how well these and other models describe these systems is being tested by several computational groups at present.^{14,15} Potential energy surfaces are calculated for a model system, and the Hamiltonian is then numerically diagonalized. A Boltzmann population-weighted average over the calculated exchange splittings is computed for comparison to the experimentally observed variation of J with temperature. Such calculations can be made to reproduce the trends observed experimentally. However, it remains to be seen how high a level of calculation will be needed to do a better job than the approximate analytical theories.

4 EXAMPLES

A large number of transition metal hydride systems that display exchange couplings have been discovered or rediscovered. One of the most striking is the $\text{Cp}^*(\text{CO})\text{IrH}_3^+$ cation. At 500 MHz, spectra similar to the simulations shown in Figure 3 are observed.¹⁶ This is a deceptively simple AB_2 spectrum, which at first glance is a single line. On closer inspection, one sees that the central line is flanked by two broader lines with integrated intensities of approx. one-tenth of the central peak. This is an example of a dynamically broadened spectrum with a very large $J(^1\text{H}, ^1\text{H})$. The apparent

Figure 3 Simulated AB_2 dynamic 1H NMR spectra similar to what are observed at 500 MHz and about 140 K for the $Cp^*(CO)IrH_3^+$ cation.¹⁶ $J = -2J$ in these simulations is (a) 50 kHz, (b) 25 kHz, and (c) 18 kHz. The central line appears at the weighted average of the A and B chemical shifts. One of the dynamically broadened wings appears at the A-site chemical shift. In comparison with the experimental spectra, only simulations with $J = -2J > 50$ kHz produce a narrow enough central peak. In such cases where $|\nu_A - \nu_B| \ll J$, the central line does not broaden as the decoalescence temperature is reached—rather, only the outer wings narrow. This can lead to the impression that such a molecule is fluxional when in fact it is not

$J = -2J$ must be over 50 kHz as judged from comparison of these simulations with the experimental spectra. This large J lead us to predict that the exchange interaction in the perdeutero system would be of the order of 30–60 Hz and thus observable. Figure 4 shows an example of 2D – 2D exchange coupling observed in this molecule. Simulation of this spectrum requires an exchange coupling. This is because, for spin $I = 1$, the Hamiltonian no longer has the same symmetry as a scalar coupling; therefore, these data cannot be simulated using a scalar coupling network. From the dependence of J on T , one can extract the parameters a and ν , which predict that $J(^1H, ^1H)$ should be approx. 75 kHz, in accordance with the observed 1H spectra. In future, it will be important to find systems in which both the 1H and 2D exchange interactions can be accurately measured as a test of exchange coupling theories.

As a final example, Figure 5 displays some calculated 2D exchange-coupled spectra for AB_2 spin systems with various ratios of exchange coupling to the chemical shift difference. A D_B – D_B scalar coupling has also been included. Note that the scalar coupling between two magnetically equivalent nuclei is now seen to have an effect upon the spectrum! This result is expected, since the D_A – D_B exchange interactions do not commute with the D_B – D_B scalar coupling Hamiltonian, making it possible now to observe it in the spectra.

Figure 4 (a) Experimental 2D NMR spectrum of a mixture of deuterated isotopomers of the $Cp^*(CO)IrH_3^+$ cation (approx. 60% D) at about 145 K. (b) Simulated spectrum giving a D–D exchange coupling between the A and B sites of approx. 40 Hz. Such spectra cannot be fitted using a scalar coupling network

5 SUMMARY

Exchange couplings in solution NMR spectra are manifestations of a purely quantum mechanical effect on the energy levels of sets of identical nuclei in molecules. These effects are related to rotational tunnel splittings in systems such as H_2 or methyl groups, and have the same origins as quantum exchange in solid 3He . The unique feature of exchange coupling in transition metal polyhydride systems is that it persists to relatively high temperatures in the solution phase, making it possible to observe very small exchange splittings by

Figure 5 Calculated ^2D NMR spectra for an AB_2 spin system with scalar and exchange couplings (the chemical shift difference has been set at 400 Hz): (a) no couplings; (b) scalar couplings $J(\text{A}, \text{B}) = 30$ Hz, $J(\text{B}, \text{B}) = 0$; (c) scalar couplings $J(\text{A}, \text{B}) = 30$ Hz, $J(\text{B}, \text{B}) = 100$ Hz; (d) AB exchange coupling $|-2J| = 30$ Hz, scalar $J(\text{B}, \text{B}) = 0$; (e) AB exchange coupling $|-2J| = 30$ Hz, scalar $J(\text{B}, \text{B}) = 100$ Hz. Note that in (c) the inclusion of $J(\text{B}, \text{B}) = 100$ Hz has no visible effect, while the spectrum in (e) is dramatically different from that in (d) when $J(\text{B}, \text{B})$ is introduced

high-resolution NMR. While these splittings are related to tunnel splittings, they do not imply that coherent tunneling motions occur. Rather, they are a consequence of shifts in the orbital energies of the nuclei that are correlated with their spin states. This correlation of spatial and spin variables results in the exchange energy appearing in the transition frequencies observed in NMR spectra.

Acknowledgments

My work in this area has benefited from many interactions with NMR spectroscopists, inorganic chemists, and theoreticians interested in transition metal hydride chemistry. Especially important to me has been my close and very enjoyable collaboration with Professor D. Michael Heinekey and his group. Without his careful attention to experimental detail, the phenomenon of exchange coupling in solution NMR spectra would probably still remain undiscovered.

Biographical Sketch

1 INTRODUCTION

A long time has passed since the formulation of relativistic quantum mechanics. Meanwhile, it has become chemistry textbook knowledge that atoms and molecules containing heavy nuclei exhibit so-called relativistic effects which, e.g., cause mercury to be liquid and are responsible for the color and the chemical inertness of gold. A qualitative explanation based on the Bohr model for one-electron atoms is straightforward. Special relativity has to be considered when velocities are no longer small compared to the speed of light. The Bohr formulae can be interpreted such that, in atomic units (see below), the electron in the ground state has a velocity of Z , with Z being the nuclear charge. The speed of light, c , has a value of approximately 137 in the same units. This illustrates that electrons in heavy atoms can reach a substantial fraction of the speed of light, and it is therefore clear that core orbitals in heavy atoms show sizable relativistic effects. It has been somewhat surprising, however, that valence orbitals exhibit relativistic effects of the same order in c^{-2} as core orbitals, which cause significant changes in the chemical properties of heavy element compounds. Relativistic effects for valence orbitals are nowadays well investigated and understood. For elements of the 6th row of the periodic table (Cs–Rn), the correction terms are so large that nonrelativistic quantum chemical computations often do not yield even a qualitatively correct answer. It is generally accepted that relativistic computations have to be carried out for such atoms and their compounds. c^{-2} appears in the relativistic theory – due to its smallness – as an expansion parameter, by which perturbational orders of relativistic corrections are

characterized. The nonrelativistic limit is approached for $c \rightarrow \infty$.

Nuclear shieldings and spin–spin couplings are very sensitive experimental probes for the electronic and geometrical structure of a compound. For the same reason, however, they are difficult to compute accurately. In the presence of heavy nuclei, any attempt to achieve a reasonable agreement between theory and experiment has to consider relativistic effects in the computations. Both the current state of relativistic quantum chemical methods and the art of computing NMR parameters have advanced far enough that a large body of computational results for heavy element systems obtained with a variety of methods is available. Remarkable results have been achieved, e.g., the explanation of certain experimental trends such as the ‘halogen dependence’, or the ability to compute NMR parameters with the heavy nuclei as the probe. Therefore it is appropriate to give a short overview here of the methodologies being used so far as well as results that have been obtained for a number of heavy atom systems.

Concerning the methodology, we focus on methods that are capable of treating both light and heavy nuclei with respect to NMR shieldings and spin–spin couplings on a first-principles basis (meaning *ab initio* methods and approximate Kohn–Sham density functional theory (DFT)). Variational methods are emphasized, but the possibility of treating relativity as a perturbation is frequently mentioned. In particular for nuclear shieldings, certain chemical trends have successfully been explained upon inclusion of spin-orbit coupling to first order alone, and a number of such results are quoted in Section 3. Concerning the spin–spin couplings, we focus on couplings involving a heavy nucleus. Dimensionless atomic units (unit of charge $e = 1$, electron mass $m = 1$, $4\pi\epsilon_0 = 1$, $\hbar = 2\pi$, $c \approx 137.036$) are used in the theoretical section. The electronic g -factor is assumed to be exactly 2, as predicted by the Dirac equation, and not written explicitly.

Computed or experimental nuclear shieldings and chemical shifts are quoted in ppm (10^{-6}), spin–spin couplings either as reduced couplings K in SI units of $\text{kg m}^{-2} \text{s}^{-2} \text{A}^{-2}$, or as coupling constants J in Hertz (s^{-1}). The discussion of theoretical results and interpretations refer to a time-independent treatment of closed-shell molecules with fixed nuclei.

In Section 2, we outline the theoretical approach to heavy atom NMR. Illustrative results and interpretations for chemical shifts and spin–spin couplings presented in Sections 3 and 4, respectively, are chosen in order to cover a range of chemical applications and trends and a number of different methodologies.

2 RELATIVISTIC THEORY OF NMR SHIELDINGS AND SPIN–SPIN COUPLING CONSTANTS

In this section the theoretical methodology that allows for the relativistic computation of NMR parameters of molecules is outlined. Due to the vast amount of literature and the many different techniques in the field of relativistic quantum chemistry, no attempt has been made to give a complete overview. Instead, a hierarchy of currently common approximations from which magnetic properties can be extracted is sketched in a pragmatic way. For details we refer to some of the books and review articles on relativistic quantum chemistry.^{1–4}

2.1 Relativity in Quantum Chemistry

‘Ordinary’ nonrelativistic quantum chemistry deals with the solution of the time-independent many-electron Schrödinger equation

$$\hat{\mathcal{H}}^{\text{nr}}\Psi = \Psi E \quad (1)$$

where Ψ is the many-electron wavefunction of an atom or molecule with fixed nuclei, and E is the total energy.

$$\hat{\mathcal{H}}^{\text{nr}} = \sum_{i=1} \frac{\hat{\mathbf{p}}_i^2}{2} + \sum_{i=1} V_{Ni} + V_{ee} + V_{\text{nuc}} \quad (2)$$

is the nonrelativistic Hamiltonian consisting of the nonrelativistic kinetic energy operator $\hat{\mathbf{p}}_i^2/2$ for each electron i , the electron-nucleus attraction potential V_{Ni} for each electron, the nonrelativistic electron–electron Coulomb repulsion $V_{ee} = \sum_{j>i} 1/r_{ij}$, and the internuclear repulsion potential V_{nuc} . $\hat{\mathbf{p}} = -i\nabla$ is the momentum operator in space representation. Since analytic solutions of equation (1) for many electron systems are not known, approximations have to be made. As a starting point, the N -electron equation is usually separated into N effective one-electron equations for one-particle wavefunctions ψ (so called atomic or molecular orbitals) which depend on an effective potential V . For simplicity, we implicitly refer to such effective one-electron equations (or true one-electron systems) in the following, by using the symbol ψ for the one-electron wavefunction or orbital. Particular details of common approximations are not discussed in this section.

In relativistic quantum chemistry, $\hat{\mathcal{H}}^{\text{nr}}$ in equation (1) is replaced by its relativistic counterpart. All of the problems of the nonrelativistic many-electron theory are present in the relativistic formulation as well. Hence, similar techniques are common in order to find approximate solutions; in particular, use of orbitals is made. However, relativistic quantum chemistry has its own specific problems associated with it, one of them being the lack of a consistent relativistic many-particle Hamiltonian being derived from quantum electrodynamics. Therefore, relativistic many-electron atomic and molecular computations rely on the use of the four-component ‘no-pair’ Dirac–Coulomb–Breit Hamiltonian or some approximation obtained from it:

$$\hat{\mathcal{H}}^{\text{DCB}} = \hat{P}^+ \left[\sum_{i=1}^N (c\boldsymbol{\alpha}_i \hat{\mathbf{p}}_i + \beta_i c^2) + V_{Ni} + V_{ee} + \sum_{j>i=1}^N \hat{\mathcal{H}}_{ij}^{\text{B}} + V_{\text{nuc}} \right] \hat{P}^+ \quad (3)$$

Here, $\boldsymbol{\alpha}$ and β are 4×4 matrices introduced by Dirac in order to obtain a relativistic wave equation for spin-1/2 particles from the ‘classical’ relativistic Hamilton function. In its standard representation, $\boldsymbol{\alpha}$ is written in terms of the well-known Pauli spin-matrices $\boldsymbol{\sigma}_s$ (not to be confused with the symbol for the nuclear shielding tensor). The $\hat{\mathcal{H}}_{ij}^{\text{B}}$ (Breit interaction, see, e.g., Ref.⁴) are relativistic corrections to V_{ee} that contain the so-called magnetic interaction and further account for the fact that the electron–electron interaction is not instantaneous but is transmitted with a finite speed. Use of the projection operators $\hat{P}^+$ cures some of the problematic

features of the Dirac–Coulomb(–Breit) operator by restricting its solutions to the positive energy spectrum, the eigenfunctions of which are identified with the desired electronic states (no-pair approximation^{2,5}). We have to stress here that though $\hat{\mathcal{H}}^{\text{DCB}}$ is in general not truly Lorentz invariant, it “provides an excellent approximation to the full theory”.³

The main difference between the four-component relativistic and the nonrelativistic Hamiltonian is seen to be in the kinetic energy operator for an electron, which is $c\boldsymbol{\alpha}\hat{\mathbf{p}} + \beta c^2$ in equation (3) instead of $\hat{\mathbf{p}}^2/2$ in $\hat{\mathcal{H}}^{\text{nr}}$. It takes into account the relativistic increase of electron mass due to high velocities, it includes the electron’s rest mass energy, it incorporates the electron spin, and also causes the spin-orbit coupling. Although electron spin needs to be considered in the nonrelativistic theory in an ad hoc manner in order to account for experimental facts, a coupling between spin and spatial degrees of freedom occurs only in the relativistic theory. For simplicity of notation, we omit the $\hat{P}^+$ in the following, and we do not explicitly consider the Breit interaction since it is actually being neglected in many computations. Its relative importance to, e.g., total atomic energies was found to decrease with increasing nuclear charge from $\sim 50\%$ in He to $\sim 2\%$ in Hg relative to the one-electron relativistic corrections.⁶

A conceptually straightforward way of performing a relativistic molecular computation in order to obtain a starting point for a calculation of NMR properties is to use directly the time-independent Dirac equation

$$\hat{\mathcal{H}}^{\text{D}}\psi^{\text{D}} = \psi^{\text{D}} E \quad (4)$$

with

$$\hat{\mathcal{H}}^{\text{D}} = c\boldsymbol{\alpha}\hat{\mathbf{p}} + \beta c^2 + V \quad (5)$$

Note that we used here the aforementioned simple notation for (effective) one-electron equations. ψ^{D} is a four-component relativistic orbital. Because $\boldsymbol{\alpha}$ and β are 4×4 matrices, the wavefunction has to be a four-component vector for which each component is a complex function of space. Due to the four components, such molecular computations are unfortunately quite expensive as compared to nonrelativistic ones, and the explicit inclusion of electron correlation is a formidable task.

Many attempts have been made to transform the four-component equation (4) into two-component form, in order to keep interpretations simpler and to reduce the computational effort. However, so-called picture change effects occur, a discussion of which is beyond the scope of this overview (see, e.g., Ref.⁷ and references cited therein.) Here we give an account of some of these methods. Writing $\boldsymbol{\alpha}$ explicitly in terms of the 2×2 Pauli spin-matrices $\boldsymbol{\sigma}_s$, the Dirac equation (4) reads

$$(\hat{\mathcal{H}}^{\text{D}} - E)\psi^{\text{D}} = \begin{pmatrix} V - E & c\boldsymbol{\sigma}_s \hat{\mathbf{p}} \\ c\boldsymbol{\sigma}_s \hat{\mathbf{p}} & V - E - 2c^2 \end{pmatrix} \begin{pmatrix} \varphi \\ \chi \end{pmatrix} = 0 \quad (6)$$

The zero of the energy scale has been shifted in equation (6) to $+mc^2$, $m = 1$, the rest mass energy of the electron, so that bound states have negative energy as usual in nonrelativistic quantum chemistry. Here, φ and χ are the so-called ‘upper’ and ‘lower’ components of the four-component orbital ψ^{D} , each of them made up of two components. The functions φ

and χ are also frequently referred to as the ‘large’ and ‘small’ components because of the $1/2c$ prefactor in equation (7) below. (Note, however that, depending on the potential and the location, the ‘small component’ can be much larger than the ‘large’ one, e.g., for $p_{1/2}$ orbitals close to the nucleus.) From the second row of the matrix one obtains explicitly

$$\chi = X\varphi = \frac{1}{2c}k\sigma_s\hat{p}\varphi \quad (7)$$

with $k = (1 - [(V - E)/2c^2])^{-1}$, which yields the relation between the upper and the lower component. Because φ and χ are not independent of each other, it should be possible to obtain a relativistic two-component equation for φ or χ alone, the solutions of which contain the same information as ψ^D . In the elimination of the small component (ESC) scheme, equation (7) is directly substituted in the equation obtained from the first row of the matrix in (6) and yields the two-component Hamiltonian:

$$\hat{\mathcal{H}}^{\text{ESC}} = V + \frac{1}{2}(\sigma_s\hat{p})k(\sigma_s\hat{p}) \quad (8)$$

In the nonrelativistic limit, $c \rightarrow \infty$, $k \rightarrow 1$, and then, with $(\sigma_s\hat{p})^2 = \hat{p}^2$, the nonrelativistic Schrödinger Hamiltonian is recovered from the ESC operator (8):

$$\hat{\mathcal{H}}^{\text{nr}} = V + \frac{1}{2}(\sigma_s\hat{p})^2 \quad (9)$$

Another way in which to obtain the nonrelativistic limit is to multiply (4) with $\hat{\mathcal{H}}^D$ before taking the limit $c \rightarrow \infty$. Although the ESC equation appears to be very illustrative, the Hamiltonian depends (through k) on the unknown energy and is not usable in actual linear variational calculations. In order to arrive at an energy-independent two-component equation, the Foldy–Wouthuysen (FW) transformation of $\hat{\mathcal{H}}^D$ to block-diagonal form is achieved by

$$\hat{\mathcal{H}}^{\text{FW}} = U\hat{\mathcal{H}}^D U^{-1} \quad (10)$$

When $\hat{\mathcal{H}}^{\text{FW}}$ is block diagonal, this completely uncouples the upper and lower component and yields the desired two-component equation and $\chi = X\varphi$, an energy-independent relation between upper and lower component [see equation (7)]. U can be written in terms of X , see, e.g., the literature cited in Ref.⁷ For many-electron systems, the exact form of X and U and therefore the exact form of $\hat{\mathcal{H}}^{\text{FW}}$ are not known. Different approximations for X yield different approximate two-component Hamiltonians in which the uncoupling of the two components is only achieved to a certain order in c^{-2} . These approximate two-component Hamiltonians are sometimes collectively denoted as ‘quasi relativistic’.

A rather simple approach is to expand (7) to zeroth order in c^{-2} . This yields $X \approx c\sigma_s\hat{p}/2c^2$, which results in the famous Pauli Hamiltonian⁸ after carrying out the transformation (10) with $U(X)$:

$$\hat{\mathcal{H}}^{\text{Pauli}} = \hat{\mathcal{H}}^{\text{nr}} - \frac{\hat{p}^4}{8c^2} - \frac{(\hat{p}^2 V)}{8c^2} + \frac{i}{4c^2}\sigma_s[(\hat{p}V) \times \hat{p}] \quad (11)$$

The second, third, and fourth term on the right-hand side of (11) are the mass–velocity (MV), Darwin (DAR), and

spin-orbit (SO) terms, respectively, representing corrections of order c^{-2} to the nonrelativistic Hamiltonian. The Pauli operator has certain pathological features due to the fact that close to a nucleus where V is very large (it goes to $-\infty$ for point-like nuclei), $(V - E)/2c^2$ is not small and neglecting this term in equation (7) is not justified. As a result, the Pauli operator affords severe singularities. Moreover, it is not variationally stable and permits only a perturbational treatment to first order. Higher order contributions yield diverging terms. Variational computations based on the Pauli operator have been frequently carried out, by using frozen cores and minimal basis sets in the core regions for valence orbitals, under which circumstances the variational instability can be kept somewhat under control in many cases. We refer to such frozen core methods in Sections 3 and 4 when speaking about variational Pauli computations. A *scalar relativistic* approach is obtained by omitting the SO term. This yields a one-component formalism analogous to the nonrelativistic scheme with pure α - and β -spin orbitals, that contain the – in many cases dominant – scalar relativistic effects. It is also possible to separate off a spin-orbit part in the Dirac equation.

One of the possible alternatives for the Pauli Hamiltonian is offered by the so-called zeroth order regular approximation (ZORA) method.⁹ Some authors refer to the ZORA Hamiltonian as the Chang–Pélissier–Durand (CPD) operator. It is obtained from the zeroth order of an expansion of k in powers of $E/(2c^2 - V)$ in equation (7). This expansion parameter remains rather small in particular where the potential V goes to $-\infty$. The two-component ZORA Hamiltonian resulting from the transformation (10) reads

$$\hat{\mathcal{H}}^{\text{ZORA}} = V + \frac{1}{2}(\sigma_s\hat{p})\mathcal{K}(\sigma_s\hat{p}) \quad (12a)$$

$$= V + \frac{1}{2}\hat{p}\mathcal{K}\hat{p} + \frac{i}{2}\sigma_s[(\hat{p}\mathcal{K}) \times \hat{p}] \quad (12b)$$

with $\mathcal{K} = 2c^2/(2c^2 - V)$. Note the formal similarity to the ESC Hamiltonian in (8), with k replaced by $\mathcal{K}$. The nonrelativistic limit corresponds to $\mathcal{K} \rightarrow 1$, $(\hat{p}\mathcal{K}) = 0$. The first and the second term in (12b) yield $\hat{\mathcal{H}}^{\text{nr}}$ plus scalar relativistic corrections, while the third term is the ZORA SO operator. For small V , $(\hat{p}\mathcal{K}) \approx (\hat{p}V)/2c^2$, and the ZORA SO term is similar to the Pauli SO term. Close to a nucleus, both operators differ substantially. The use of the ZORA method in heavy element computations is becoming increasingly popular, and the results are in most cases superior to those obtained with the Pauli operator. Conceptually, the ZORA operator has the disadvantage of not being invariant with respect to a change of the origin of the energy scale (gauge invariance), as can be seen from the fact that only V but not $(V - E)$ occurs in the operator. The standard choice for the potential is $V(\mathbf{r}) \rightarrow 0$ for $\mathbf{r} \rightarrow \infty$. Most of the resulting problems can be circumvented by a ‘scaling’ procedure or by the use of frozen core potentials or model potentials for the construction of $\mathcal{K}$.

A different way of transforming the Dirac Hamiltonian to two-component form is used in the Douglas–Kroll (DK) method. Here, U in equation (10) is obtained via subsequent transformations that uncouple the upper and lower components to some order n in c^{-2} written as

$$U_n = \sqrt{1 + W_n^2} + W_n \quad (13)$$

where W_n is anti-hermitian. For U_0 , the FW transformation for the free electron is used. To higher orders, equations for W_n have to be solved in order to achieve further uncoupling. Already with U_1 , most of the relativistic effects are recovered. We refer the reader to, e.g., Ref.³ for details and original references. In particular due to the work of Hess and co-workers, the DK method has been established as a reliable tool in quantum chemistry for the computation of heavy element compounds. To some extent, the ZORA and the DK method to lowest order yield quite comparable results for many molecular properties. As an advantage, the DK method does not suffer from a gauge invariance problem, at the disadvantage of a somewhat more complicated formalism, if spin-orbit coupling and magnetic fields are included.

In order to arrive at a relativistic perturbation theory that avoids the infinities of the Pauli Hamiltonian to higher orders, so-called ‘direct’ or ‘Dirac’ four-component perturbation theory (DPT) can be employed. By a simple change of metric between upper and lower components in the Dirac equation (6), an expansion of the resulting four-component equation in powers of c^{-2} is straightforward and leads to non-singular first and higher order expressions for E and ψ . A treatment of magnetic properties has been described in detail in the literature.¹⁰ However, higher order expressions become computationally rather expensive, while at the same time it is well known that first-order relativistic perturbation theory is not sufficient for such ‘relativistic’ elements as, e.g., Au, Hg or Pb for the determination of bond energies or molecular geometries. It can be assumed that relativistic corrections up to order c^{-4} at least are also necessary for NMR parameters for such nuclei, in which case a variational procedure (Dirac, ZORA, DK) might be easier to implement and computationally not much more or even less expensive.

As an alternative to the aforementioned methods which incorporate relativity directly into the calculations, the use of relativistic effective core potentials (ECPs) allows for consideration of relativistic effects in molecular computations. Inclusion of spin-orbit coupling is also possible in these methods. Recent benchmark calculations¹¹ have shown that ECPs can yield very reliable properties of heavy element compounds.

As already mentioned, the potential V in the equations in this section might not simply refer to the external potential (e.g., V_{Nf}) for one-electron systems but to an effective many-electron potential. In this case, V implicitly contains effects that are due to the electron–electron Coulomb repulsion $1/r_{ij}$. The explicit transformation of $1/r_{ij}$ to two-component form yields new relativistic operators of order c^{-2} instead, for example the two-electron spin-orbit operator. Use of the effective electronic potential in V in the one-electron SO operator accounts, to some extent, for these two-electron terms in a mean-field sense. Transformation of the Breit interaction to two-component form yields further two-electron terms, such as the spin-other-orbit operator.

2.2 Nuclear Shieldings and Spin–Spin Couplings

A basic quantity that formally allows access to many properties of atoms and molecules is the total (electronic + nuclear repulsion) energy E of the system. It is readily available, to some degree of accuracy depending on the approximations that have been made, from quantum chemical

computations, either from a relativistic or nonrelativistic formalism, based on variational or perturbational approaches. We refer to the wavefunction or the set of orbitals that produced this energy as the ‘zeroth order solution’. In practice, it does not initially contain the effects from external magnetic fields or nuclear spins, but it might incorporate relativistic effects. Many observables, among them NMR shielding and spin–spin coupling tensors, can be defined as derivatives of the total energy of the system under investigation. The shielding tensor σ for a nucleus A is given by

$$\sigma(A) = \left. \frac{\partial^2 E}{\partial \mathbf{B}^{\text{ext}} \partial \boldsymbol{\mu}_A} \right|_{\mathbf{B}^{\text{ext}}=0, \boldsymbol{\mu}_A=0} \quad (14a)$$

while the reduced nuclear spin–spin coupling tensor $\mathbf{K}$ involving two nuclei A and B is obtained from

$$\mathbf{K}(A, B) = \left. \frac{\partial^2 E}{\partial \boldsymbol{\mu}_A \partial \boldsymbol{\mu}_B} \right|_{\boldsymbol{\mu}_A=0, \boldsymbol{\mu}_B=0} \quad (14b)$$

Here, $\mathbf{B}^{\text{ext}}$ is the applied external magnetic field, and $\boldsymbol{\mu}_A$ is the magnetic moment of nucleus A , related to its intrinsic angular momentum $\mathbf{I}_A$ by $\boldsymbol{\mu}_A = \gamma_A \hbar \mathbf{I}_A$ with γ_A being the magnetogyric ratio of the nucleus. We refer to some of the many excellent review articles focusing on the nonrelativistic computation of NMR parameters for details.^{12–15} Equations (14a,b) conceptually serve as the starting point for a perturbational approach by which the energy derivatives can be evaluated once the zeroth order solution has been obtained. For the spin–spin coupling, the direct (through space) coupling between two nuclei does not yield a contribution to the coupling constants for rapidly rotating molecules (i.e., for measurements in gas phase or in solution) and is not discussed further. We implicitly refer to indirect spin–spin couplings throughout the rest of this article.

For the general case of two perturbations, described by the perturbation parameters $\boldsymbol{\kappa}$ and $\boldsymbol{\lambda}$ with Cartesian components $\kappa_x, \kappa_y, \kappa_z$ etc., the mixed second derivative of the total energy

$$E = \langle \Psi | \hat{\mathcal{H}} | \Psi \rangle \quad (15)$$

with respect to the perturbation parameters is given from standard double perturbation theory by equation (16). There it is assumed that the Hellmann–Feynman theorem holds with respect to the first perturbation $\boldsymbol{\lambda}$ for approximate zeroth-order solutions. In the NMR case, the nuclear magnetic moments or the external magnetic field are directly interpreted as the perturbation parameters due to their relative ‘smallness’.

$$\begin{aligned} E^{(1,1)} &= \left. \frac{\partial^2 E}{\partial \boldsymbol{\kappa} \partial \boldsymbol{\lambda}} \right|_{\boldsymbol{\kappa}=0, \boldsymbol{\lambda}=0} \\ &= \langle \Psi^{(0,0)} | \hat{\mathcal{H}}^{(1,1)} | \Psi^{(0,0)} \rangle + 2\text{Re} \langle \Psi^{(0,1)} | \hat{\mathcal{H}}^{(1,0)} | \Psi^{(0,0)} \rangle \end{aligned} \quad (16)$$

The superscripts denote the order of perturbation with respect to $\boldsymbol{\lambda}$ and $\boldsymbol{\kappa}$, respectively. Because $\boldsymbol{\lambda}$ and $\boldsymbol{\kappa}$ are vectors, $E^{(1,1)}$ is a 2nd rank tensor. $\hat{\mathcal{H}}^{(1,0)} = \partial \hat{\mathcal{H}} / \partial \boldsymbol{\lambda}|_{\boldsymbol{\lambda}=0}$, $\Psi^{(0,1)} = \partial \Psi / \partial \boldsymbol{\kappa}|_{\boldsymbol{\kappa}=0}$, etc. $\Psi^{(0,1)}$ represents the change of the wavefunction due to the presence of the perturbation denoted by $\boldsymbol{\kappa}$, i.e., either the external magnetic field, or the magnetic field arising from one

of the nuclear spins. $\Psi^{(0,1)}$ can be formally obtained from solving the first-order perturbed wave equation

$$(\hat{\mathcal{H}}^{(0,0)} - E^{(0,0)})\Psi^{(0,1)} + (\hat{\mathcal{H}}^{(0,1)} - E^{(0,1)})\Psi^{(0,0)} = 0 \quad (17)$$

showing that $\hat{\mathcal{H}}^{(0,1)}$ has to be known in order to compute $\Psi^{(0,1)}$. In DFT, formally similar expressions involving a sum over the Kohn-Sham orbitals instead of the many-electron wavefunction Ψ are used to compute σ and $\mathbf{K}$.

In the sum-over-states formulation it is assumed that the unperturbed ground state $\Psi_0 = \Psi^{(0,0)}$ with $E_0 = E^{(0,0)}$ and all the excited states (energies E_i and wavefunctions Ψ_i) corresponding to the field-free Hamiltonian $\hat{\mathcal{H}}^{(0,0)}$ are known. The Ψ_i form a complete basis set in which $\Psi^{(0,1)}$ can be expressed as

$$\Psi^{(0,1)} = \sum_{a \neq 0} \Psi_a C_a \quad (18)$$

with yet unknown coefficients C_a . With the first-order equation (17), one obtains for the C_a after some manipulation

$$C_a = \sum_{a \neq 0} \frac{\langle \Psi_a | \hat{\mathcal{H}}^{(0,1)} | \Psi_0 \rangle}{E_0 - E_a} \quad (19)$$

and therefore for the nuclear shielding or spin-spin coupling

$$E^{(1,1)} = \langle \Psi_0 | \hat{\mathcal{H}}^{(1,1)} | \Psi_0 \rangle + 2\text{Re} \sum_{a \neq 0} \frac{\langle \Psi_0 | \hat{\mathcal{H}}^{(0,1)} | \Psi_a \rangle \langle \Psi_a | \hat{\mathcal{H}}^{(1,0)} | \Psi_0 \rangle}{E_0 - E_a} \quad (20)$$

We have to stress here that although equation (20) is *formally* correct, in practice not all (or any) of the excited states of $\hat{\mathcal{H}}^{(0,0)}$ are (or can be) known. However, equation (20) serves as a convenient basis for an interpretation of the final results and approximations to it can be easily identified within orbital models. Employing variational perturbation theory, $E^{(1,1)}$ is in practice usually directly computed from the zeroth order solution based upon the set of occupied and unoccupied (virtual) orbitals that serve as a one-particle basis in most theoretical methods.¹⁶ In simple cases, for each occupied orbital a sum over virtual orbitals similar to (20) can be derived as the contributions to $E^{(1,1)}$, in which $E_0 - E_a$ is replaced by differences between occupied and virtual orbital energies, $\epsilon_i - \epsilon_a$. However, these orbital contributions also take into account possible first-order change in the potential caused by the perturbation, and a possible dependence of the basis set on the perturbation. Neglecting any change in the potential V leads to so-called uncoupled equations that are much easier and computationally cheaper to solve. (In DFT, neglecting the current-density dependence of the density functional leads to the mentioned uncoupled approach when the first-order perturbations of the orbitals due to the external magnetic field are evaluated.) For interpretation purposes, the potential change is often negligible, in which case the orbital contributions can have exactly the form (20), but with Ψ_0 replaced by an occupied orbital ψ_i (with energy ϵ_i) and Ψ_a and E_a replaced by virtual orbitals ψ_a and their energies ϵ_a . In particular the HOMO-LUMO gap plays an important role here, since it leads to the largest individual

$1/(\epsilon_i - \epsilon_a)$. Another factor is, of course, the magnitude of the $\langle \psi_i | \hat{\mathcal{H}}^{(0,1)} | \psi_a \rangle$ and $\langle \psi_a | \hat{\mathcal{H}}^{(1,0)} | \psi_i \rangle$ matrix elements. For chemical shifts (not shieldings) and spin-spin couplings, it turns out that $\langle \Psi_0 | \hat{\mathcal{H}}^{(1,1)} | \Psi_0 \rangle$, the diamagnetic term (see below), is often of only minor importance. It is also possible to write the diamagnetic term in a sum-over-states form.¹⁷ *For simplicity of notation, we refer to equation (20) as the working equation for evaluating σ and $\mathbf{K}$ regardless of the actual method being used.*

Once the zeroth order solution is known, and the perturbation operators with respect to μ_A and $\mathbf{B}^{\text{ext}}$ have been formulated, σ and $\mathbf{K}$ can be computed based on equation (20) in some chosen computational approximation. For the relativistic case of heavy element systems, E , Ψ and the perturbation operators refer to a relativistic zeroth-order treatment. In case relativity is treated as a perturbation itself, this leads to at least second- and third-order perturbation expressions for σ and $\mathbf{K}$ in which the order of derivatives is arbitrary. In this case, relativity can be conceptually regarded as a perturbation of an initially nonrelativistic expression for (14a,b).

In order to apply equation (20) for the computation of NMR shieldings or spin-spin couplings, the presence of the external magnetic field $\mathbf{B}^{\text{ext}}$ and the magnetic field due to the nuclear spins has thus to be considered in the theory. More specifically, within a chosen theoretical level (nonrelativistic, four-component, a variational two-component scheme, relativistic perturbation theory, ...) the Hamiltonian $\hat{\mathcal{H}}(\mathbf{B}^{\text{ext}}, \mu)$ is to be formulated in order to determine $\hat{\mathcal{H}}^{(1,1)}$, $\hat{\mathcal{H}}^{(1,0)}$ and $\hat{\mathcal{H}}^{(0,1)}$. Magnetic fields $\mathbf{B}$ are usually incorporated into quantum chemistry by finding the corresponding magnetic vector potential $\mathbf{A}$ which is related to the magnetic field $\mathbf{B}$ by $\mathbf{B} = \nabla \times \mathbf{A}$, and making the so-called minimal substitution for the momentum operator in the field-free Hamiltonian,

$$\hat{\mathbf{p}} \longrightarrow \hat{\boldsymbol{\pi}} = \hat{\mathbf{p}} - q\mathbf{A} \quad (21)$$

with respect to a particle of charge q . We use $q = -e = -1$ for an electron in the following.

The well-known gauge-invariance problem arises here, viz. a given magnetic field does not uniquely define the vector potential, since adding the gradient $\nabla f(\mathbf{r})$ of any scalar function to $\mathbf{A}$ does not change $\mathbf{B}$, because $\nabla \times \nabla f(\mathbf{r}) = 0$. Often, f is chosen such that $\nabla \mathbf{A} = 0$ (Coulomb gauge). We use this gauge in the following. A different gauge of $\mathbf{A}$ can, e.g., be represented by choosing a different origin for the coordinate representation of $\mathbf{A}$. Although for a large class of variationally determined *exact* wavefunctions, expectation values do not depend on the chosen gauge, this is not generally true for approximate wavefunctions in a finite basis.¹⁶

For a point-like nuclear magnetic dipole, the vector potential is

$$\mathbf{A}_A^\mu = \frac{1}{c^2} \frac{\mu_A \times \mathbf{r}_A}{r_A^3} \quad (22)$$

$\mathbf{r}_A$ being the distance vector with respect to nucleus A , and r_A its length. Due to the strong inhomogeneity of $\mathbf{A}_A^\mu$, the position of the nucleus A is generally used as the origin for $\mathbf{A}_A^\mu$. The vector potential of an external, homogeneous magnetic field reads

$$\mathbf{A}^{\text{ext}} = \frac{1}{2} \mathbf{B}^{\text{ext}} \times \mathbf{r} \quad (23)$$

For a molecule with many atoms there exists no obvious gauge origin since $\mathbf{r}$ refers to an arbitrarily chosen coordinate system. Nuclear shieldings obtained with wavefunctions approximated in a finite basis depend more or less strongly on the chosen origin. The $\mathbf{A}^{\text{ext}}$ gauge problem is circumvented in, e.g., the gauge-independent or gauge-including atomic orbitals (GIAO) or the individual gauge for localized orbitals (IGLO) methods. In these methods, field dependent basis functions or molecular orbitals are employed to ensure gauge invariance of expectation values. Such distributed gauge origin methods are commonly used in computations of nuclear shieldings. Another, less effective procedure is to supplement the basis sets by functions that are chosen such as to remove the gauge dependence to some extent without being of critical importance for the determination of the energy or the molecular structure. The gauge origin problem has been extensively discussed in the literature (see, e.g., Refs.^{12,13,18} and literature cited therein for details).

Equation (22) is the most frequently used expression for the nuclear magnetic vector potential. It is known that for very accurate relativistic results, a finite nucleus model should be adopted both to obtain the zeroth-order solution as well as in the NMR perturbation calculation. However, almost all of the results quoted later in this work have been obtained with the point-nucleus approximation, and the influence of finite-nucleus corrections on the final results does not seem to be of critical importance.

Substituting (21) into the nonrelativistic one-electron Schrödinger Hamiltonian, equation (9), yields the additional ‘magnetic’ terms

$$\hat{\mathcal{H}}_{\text{nr}}^{\text{mag}} = \frac{1}{2}(\mathbf{A}\hat{\mathbf{p}} + \hat{\mathbf{p}}\mathbf{A} + i\sigma_s[\hat{\mathbf{p}} \times \mathbf{A} + \mathbf{A} \times \hat{\mathbf{p}}] + A^2) \quad (24)$$

The operators linear in $\mathbf{A}$ are called the paramagnetic terms, while those proportional to A^2 are called the diamagnetic terms. The second term on the right-hand side of equation (24) describes the interaction of the electronic spin with a magnetic field and is not present if one starts with the one-component Schrödinger equation where $(\sigma_s\hat{\mathbf{p}})^2$ of equation (9) is replaced by $\hat{\mathbf{p}}^2$ before the minimal substitution is made (this implies that the substitution $\hat{\mathbf{p}} \rightarrow \hat{\pi}$ has to be made before transformation to two-component form and then the limit $c \rightarrow \infty$ is taken). In the ZORA or ESC case, formally very similar magnetic operators are obtained that contain relativistic corrections due to the presence of $\mathcal{K}$ or k . For the ZORA case, see Refs.^{19,20} For a derivation of the magnetic terms arising from the second-order DK transformation and from the Pauli Hamiltonian, see Refs.^{21,22} The ESC case is illustrated elsewhere.²³

Substituting $\hat{\mathbf{p}}$ with $\hat{\pi}$ in the one-electron Dirac operator (5) yields a single paramagnetic term

$$\hat{\mathcal{H}}_{\text{D}}^{\text{mag}} = c\alpha\mathbf{A} \quad (25)$$

Since the nonrelativistic limit (24) as well as relativistic two-component Hamiltonians afford a diamagnetic term, this should be contained in a result for $E^{(1,1)}$ obtained from (25). It has been shown that a diamagnetic contribution to $E^{(1,1)}$ in equation (16) indeed arises in the four-component scheme due to the contributions from negative energy eigenfunctions of $\hat{\mathcal{H}}^{\text{D}}$, that are used as a basis set in a sum-over-states expression for $\Psi^{(0,1)}$ in equation (16),²⁴ even though there is only a paramagnetic perturbation operator (25).

Upon explicit substitution of $\mathbf{A} = \mathbf{A}^{\text{ext}} + \sum_A \mathbf{A}_A^\mu$ from equation (23), and equation (22) or a finite-size magnetic dipole version of it, $\hat{\mathcal{H}}^{\text{mag}}(\mathbf{B}^{\text{ext}}, \boldsymbol{\mu})$ is finally obtained. Taking the derivatives with respect to $\mathbf{B}^{\text{ext}}$ and $\boldsymbol{\mu}_A, \boldsymbol{\mu}_B$ then yields $\hat{\mathcal{H}}^{(1,1)}$, $\hat{\mathcal{H}}^{(0,1)}$ and $\hat{\mathcal{H}}^{(1,0)}$ for a specific nonrelativistic or relativistic theoretical scheme. In the case of nuclear shieldings, it is most economic to take $\hat{\mathcal{H}}^{(1,0)} = \partial\hat{\mathcal{H}}/\partial\boldsymbol{\mu}_A|_{\boldsymbol{\mu}_A=0}$, while $\Psi^{(0,1)} = \partial\Psi/\partial\mathbf{B}^{\text{ext}}|_{\mathbf{B}^{\text{ext}}=0}$. In the nonrelativistic case, one obtains the one-electron operators

$$\hat{\mathcal{H}}_{\text{nr}}^{\text{mag}}(\mathbf{B}^{\text{ext}}, \boldsymbol{\mu}) = A^{\text{ext}^2} + \hat{\mathcal{H}}^{\text{OZ}} + \hat{\mathcal{H}}^{\text{SZ}} + \hat{\mathcal{H}}^{\text{OP}} + \hat{\mathcal{H}}^{\text{DS}} + \hat{\mathcal{H}}^{\text{FC}} + \hat{\mathcal{H}}^{\text{SD}} + \hat{\mathcal{H}}^{\text{OD}} \quad (26)$$

Here,

$$\hat{\mathcal{H}}^{\text{OZ}} = \frac{1}{2}\mathbf{B}^{\text{ext}} \cdot (\mathbf{r} \times \hat{\mathbf{p}}) = \frac{1}{2}\mathbf{B}^{\text{ext}} \cdot \hat{\mathbf{L}} \quad (27a)$$

$$\hat{\mathcal{H}}^{\text{SZ}} = \frac{1}{2}\mathbf{B}^{\text{ext}} \cdot \boldsymbol{\sigma}_s \quad (27b)$$

$$\hat{\mathcal{H}}^{\text{OP}} = \frac{1}{c^2} \sum_A \boldsymbol{\mu}_A \left(\frac{\mathbf{r}_A}{r_A^3} \times \hat{\mathbf{p}} \right) \quad (27c)$$

$$\hat{\mathcal{H}}^{\text{DS}} = \frac{1}{2c^2} \sum_A \left[(\boldsymbol{\mu}_A \cdot \mathbf{B}^{\text{ext}}) \left(\frac{\mathbf{r}_A}{r_A^3} \cdot \mathbf{r} \right) - (\boldsymbol{\mu}_A \cdot \mathbf{r}) \left(\mathbf{B}^{\text{ext}} \cdot \frac{\mathbf{r}_A}{r_A^3} \right) \right] \quad (27d)$$

$$\hat{\mathcal{H}}^{\text{FC}} + \hat{\mathcal{H}}^{\text{SD}} = \frac{1}{2c^2} \sum_A \boldsymbol{\sigma}_s \left[\boldsymbol{\mu}_A \left(\nabla \cdot \frac{\mathbf{r}_A}{r_A^3} \right) - (\boldsymbol{\mu}_A \cdot \nabla) \frac{\mathbf{r}_A}{r_A^3} \right] \quad (27e)$$

$$\hat{\mathcal{H}}^{\text{OD}} = \frac{1}{2c^4} \sum_{B \neq A} \frac{(\boldsymbol{\mu}_A \cdot \boldsymbol{\mu}_B)(\mathbf{r}_A \cdot \mathbf{r}_B) - (\boldsymbol{\mu}_A \cdot \mathbf{r}_B)(\boldsymbol{\mu}_B \cdot \mathbf{r}_A)}{r_A^3 r_B^3} \quad (27f)$$

(27a) is the orbital Zeeman term, (27b) spin Zeeman, (27c) paramagnetic orbital, (27d) diamagnetic shielding, (27e) Fermi-contact + spin-dipole, (27f) diamagnetic orbital term, respectively. The individual FC and SD operators, in particular the well-known δ function for the FC term, are obtained by explicitly carrying out the differentiation of $\mathbf{r}_A/r_A^3$ in (27e). Note that the presence of c in the nonrelativistic magnetic operators does *not* denote any relativistic terms, but c emerges from the magnetic units in equation (22) and the fact that the fine structure constant equals $1/c$ in the chosen atomic units. As already mentioned, the operators in the ZORA or ESC case are formally quite similar to the nonrelativistic ones, but include $\mathcal{K}$ or k and their derivatives, yielding different spatial contributions in particular for the FC term, but similar physical interpretations. We therefore use the same names for the operators when referring to these two-component relativistic schemes.

As compared to the nonrelativistic or two-component ones, the Dirac form of the one-electron magnetic operators look rather simple:

$$\hat{\mathcal{H}}_{\text{D}}^{\text{mag}}(\mathbf{B}^{\text{ext}}, \boldsymbol{\mu}) = -\frac{c}{2}\mathbf{B}^{\text{ext}} \cdot (\boldsymbol{\alpha} \times \mathbf{r}) - \frac{1}{c} \sum_A \boldsymbol{\mu}_A \cdot \left(\boldsymbol{\alpha} \times \frac{\mathbf{r}_A}{r_A^3} \right) \quad (28)$$

Taking the derivatives with respect to $\mathbf{B}^{\text{ext}}$ and μ_A in order to apply equation (20) is conceptually straightforward. Since (26) is connected to (28) as its nonrelativistic limit, the apparent simplicity of the four-component operators results in the many two-component terms through the coupling of the upper and lower components of the wavefunction by the Dirac operators. The ‘Gordon-decomposition’ of the Dirac shielding tensor provides a route to interpret the four-component results in the more common way of paramagnetic and diamagnetic contributions.²⁵ See, e.g., Ref.²⁶ for numerical examples.

Referring to the two-component scheme, equations (27a–f), it can be seen that the OZ, OP and DS operators contribute to the nuclear shielding. Explicitly,

$$\begin{aligned}\hat{\mathcal{H}}^{(1,1)} &= \left. \frac{\partial^2 \hat{\mathcal{H}}^{\text{DS}}}{\partial \mathbf{B}^{\text{ext}} \partial \mu_A} \right|_{\mathbf{B}^{\text{ext}}=0, \mu_A=0} \\ \hat{\mathcal{H}}^{(1,0)} &= \left. \frac{\partial (\hat{\mathcal{H}}^{\text{OP}} + \hat{\mathcal{H}}^{\text{FC}} + \hat{\mathcal{H}}^{\text{SD}})}{\partial \mu_A} \right|_{\mu_A=0} \\ \hat{\mathcal{H}}^{(0,1)} &= \left. \frac{\partial \hat{\mathcal{H}}^{\text{OZ}}}{\partial \mathbf{B}^{\text{ext}}} \right|_{\mathbf{B}^{\text{ext}}=0}\end{aligned}\quad (29)$$

are used in equation (20). Here, the external field and the nuclear spin induce electronic paramagnetic orbital currents through $\hat{\mathcal{H}}^{\text{OZ}}$ and $\hat{\mathcal{H}}^{\text{OP}}$, respectively, the magnetic fields of which cause the paramagnetic nuclear shielding. The diamagnetic shielding contribution from $\hat{\mathcal{H}}^{\text{DS}}$ is due to the diamagnetic electronic currents induced in the electronic system. As already mentioned, we restrict the discussion here to the spin-compensated case (closed-shell molecules). Without spin-orbit coupling, the FC and SD terms do not contribute to the nuclear shielding in closed shell systems, i.e., with pure spin-orbitals the contributions from spin-up and spin-down orbitals due to $\hat{\mathcal{H}}^{\text{FC}}$, $\hat{\mathcal{H}}^{\text{SD}}$ exactly cancel because the external magnetic field does not induce spin density.

For nonrelativistic spin–spin couplings, one uses

$$\begin{aligned}\hat{\mathcal{H}}^{(1,1)} &= \left. \frac{\partial^2 \hat{\mathcal{H}}^{\text{OD}}}{\partial \mathbf{B}^{\text{ext}} \partial \mu_A} \right|_{\mu_A=0, \mu_B=0} \\ \hat{\mathcal{H}}^{(1,0)} &= \left. \frac{\partial (\hat{\mathcal{H}}^{\text{OP}} + \hat{\mathcal{H}}^{\text{FC}} + \hat{\mathcal{H}}^{\text{SD}})}{\partial \mu_A} \right|_{\mu_A=0} \\ \hat{\mathcal{H}}^{(0,1)} &= \left. \frac{\partial (\hat{\mathcal{H}}^{\text{OP}} + \hat{\mathcal{H}}^{\text{FC}} + \hat{\mathcal{H}}^{\text{SD}})}{\partial \mu_B} \right|_{\mu_B=0}\end{aligned}\quad (30)$$

Similar to NMR shieldings, the OP and OD terms introduce paramagnetic and diamagnetic electronic currents due to a nuclear magnetic moment that can further interact with the perturbations from another nucleus. The SD and in particular the FC term both yield nonzero contributions and cause a different coupling mechanism. These operators introduce a net electronic spin density at or around, say, nucleus A , which is transferred through the electronic system (chemical bonds) to nucleus B and interacts with its spin magnetic moment there. There is also a mixed term between the FC and the SD contribution, that contributes to the anisotropy of the $\mathbf{K}$ tensor. Again, in the nonrelativistic case, where spin and spatial degrees of freedom are completely independent from each other, all ‘mixed’ contributions to $\mathbf{K}$ between orbital-

and spin-dependent operators yield zero (e.g., the contribution due to $\hat{\mathcal{H}}^{\text{FC}}$ in $\hat{\mathcal{H}}^{(1,0)}$ with the one due to $\hat{\mathcal{H}}^{\text{OP}}$ in $\hat{\mathcal{H}}^{(0,1)}$ and vice versa in equation (20)). The same arguments concerning vanishing terms involving both spin- and orbital-dependent operators apply in the scalar relativistic case.

The situation is much different at the presence of SO coupling. Spatial and spin degrees of freedom are then coupled and not longer independent from each other. Not unexpectedly therefore, in, e.g., the Pauli, ESC, DK, or ZORA case including the one-electron spin-orbit (1e-SO) operator, mixed contributions involving both spin- and orbital-dependent operators occur for σ and $\mathbf{K}$ in this case. In particular, the spin-dependent FC and SD terms contribute to the chemical shielding because, through SO coupling, an external magnetic field induces net spin-density even in a closed-shell system. Likewise, for spin–spin couplings, mixed terms between spin- and orbital-dependent operators in $\hat{\mathcal{H}}^{(1,0)}$ and $\hat{\mathcal{H}}^{(0,1)}$ are no longer zero. In variational two-component procedures in which the zeroth-order computation and the magnetic operators are based on the same formalism and no terms have been omitted initially, no new operators or new terms in the expressions for σ or $\mathbf{K}$ arise due to SO coupling. In case that the (usually Pauli) 1e-SO operator is introduced as a first-order perturbation, the additional terms are formulated and calculated explicitly, which is convenient for interpretations. The same holds for additional scalar relativistic corrections. The operators arising from the minimal substitution $\hat{\mathbf{p}} \rightarrow \hat{\boldsymbol{\pi}}$ in the spin-orbit operator itself have thereby been overlooked for a long time.²² For nuclear shielding, the most important contribution due to spin-orbit coupling has been shown to arise from the FC term in the external magnetic field, while for spin–spin couplings, the FC-OP cross term appears to be dominant in the cases being investigated so far. See Sections 3.1 and 4.2 for further comments and explanations. All the 1e-SO contributions are, of course, contained in the four-component treatment based on equation (28).

As already mentioned, transformation of the electron–electron interaction to two-component form yields various new terms, among them the two-component two-electron spin-orbit and spin-other-orbit operators (collectively being denoted here by ‘2e-SO’), which give rise to various additional magnetic contributions in the presence of magnetic fields. See, e.g., Refs.^{4,16,27} for theoretical details. Unless explicitly mentioned, we refer to the 1e-SO effects in the following. Actual program implementations may make use of an effective potential in the 1e-SO operator and the results may therefore contain two-electron SO effects to some extent.

2.3 Computational Methods

While the importance of Hartree–Fock computations in quantum chemistry is generally decreasing in favor of either correlated ab initio methods or DFT, it is still one of the common methods in the field of computation of heavy atom NMR parameters. A four-component implementation of Hartree–Fock shielding tensors and spin–spin couplings has been reported by Visscher and co-workers^{28,29} and an implementation for nuclear shieldings by Nakatsuji and co-workers.^{26,30,31} Both implementations use a common gauge origin for the external magnetic field. Pioneering NMR Hartree–Fock calculations including scalar relativistic effects based on the Pauli operator or the DK transformation, and

spin-orbit effects based either upon explicit consideration of the Pauli SO operator or the use of spin-orbit ECPs, have been reported by Nakatsuji et al.^{32,33} and by Fukui et al.^{21,22,34} Theoretically somewhat less justified ‘mixed’ methods such as using the scalar part of the DK operator together with Pauli SO for the zeroth-order solution and nonrelativistic + Pauli SO operators for NMR shieldings have also been used with reasonable success.³⁵ The main disadvantage of the Hartree–Fock based methods is, of course, the neglect of electron correlation, that has been demonstrated to be of high importance for the determination of NMR parameters in general and of heavy atom spin–spin couplings in particular.

To the best of our knowledge, four-component post Hartree–Fock or DFT implementations of NMR parameters have not yet been carried out, but can be expected in the near future at least for the DFT case. Post Hartree–Fock MCSCF computations of heavy atom nuclear shieldings (employing GIAO) and spin–spin couplings have so far considered spin-orbit effects only, based on a perturbational first-order treatment of the Pauli SO operator.^{36–40} Scalar relativistic effects from the heavy atom were neglected in this case. This method is often suitable for NMR of light nuclei close to a heavy atom and has been successfully applied to small molecules. Likewise, SO ECPs are able to recover the important spin-orbit effects on neighbor atom shieldings that are being neglected by scalar relativistic ECPs.

The first-order SO approach has already been utilized in the pioneering approaches for the computation of nuclear shieldings in heavy atom compounds, involving simple semiempirical wavefunctions.^{41–44} For spin–spin couplings, relativistic effects have been first considered in the form of correction factors applied on top of nonrelativistic Hartree–Fock or semiempirical wavefunctions.^{45,46} Four-component extended Hückel theory (REX) has been developed and extensively applied to both heavy atom shieldings and spin–spin couplings by Pyykkö and co-workers.⁴⁷

The restriction of excluding the heavy nuclei in the NMR computations applies technically to a common use of ECPs in heavy element computations. Existing methodology for NMR parameters that has been derived for all-electron calculations cannot be used without modification for NMR parameters of those atoms for which an ECP is used. In this case, either a NMR methodology directly derived from the pseudopotential formalism would have to be used, or at least the pseudo-orbitals need to be orthogonalized on the relativistic heavy atom cores before applying a standard all-electron code.

Density functional theory (DFT)⁴⁸ has been very successful in the field of heavy atom NMR computations. Methodological development for relativistic NMR computations has been performed in particular by Kaupp, Malkin, Malkina and co-workers^{49–51} (using the IGLO method for shieldings), and by Ziegler and co-workers (GIAO for shieldings).^{19,20,52–54} Taking into account that the electron density, the spin density and the current density define the one-electron magnetic contributions to σ and $\mathbf{K}$, and that these densities are (of course only in principle) obtained exactly from Kohn–Sham DFT,⁵⁵ its application to NMR parameters has a theoretically well founded base. From the experience gained so far it seems that the current-density dependence and also relativistic corrections of the exchange–correlation functional are not very large, and quite reasonable results can be obtained with standard

nonrelativistic local-density (LDA) or generalized gradient (GGA) approximations (in which, however, the density can be a relativistic one). The fact that electron correlation is to some extent accounted for in contemporary Kohn–Sham DFT, and due to its computational effectiveness with regard to the number of atoms that can be treated simultaneously, most of the relativistic NMR computations on larger systems such as transition metal complexes are currently based on DFT. For the heavy atom DFT NMR computations carried out so far, various relativistic methods have been utilized, among them perturbational use of the Pauli SO operator, variational computations with the Pauli operator and frozen cores excluding or including SO coupling, the use of the ZORA Hamiltonian, and use of scalar relativistic and spin-orbit ECPs.

We further note that some authors subdivide the relativistic effects of NMR parameters into ‘direct’ and ‘indirect’ effects, the latter being related to the change of the NMR parameters with respect to a change of the computed molecular structure due to relativity. It is known that small geometrical changes can result in sizeable changes of shieldings and couplings. The choice of experimentally determined structures, if available, for the computations is unambiguous and leaves only the ‘direct’ effects to be discussed.

Apart from acronyms already specified in the previous sections, we make use of the following abbreviations from now on: vPSO, vPSC, vPauli for variational Pauli SO only, scalar only, and scalar + SO, respectively; similarly, pPSO, pPSC, pPauli denote first-order perturbational relativistic calculations; HF for Hartree–Fock; DKSC, DK for Douglas–Kroll, first order without and with SO corrections, respectively, and MCSCF for multiconfigurational Hartree–Fock (ab initio).

3 HEAVY ATOM NUCLEAR SHIELDINGS

Suggestions on the importance of relativistic corrections to nuclear shieldings and first numerical estimates for atoms date back to the 1960s. In 1969, Nakagawa argued that spin-orbit coupling would be an important factor for nuclear shieldings of light nuclei in the neighborhood of heavy halides.⁵⁶ Subsequently, semiempirical calculations of the respective SO effect in hydrogen and methyl halides were carried out by Morishima et al.,⁴¹ Volodicheva and Rebane⁴² and Cheremisin and Schastnev.⁴³ In the early 1980s, several authors published the formalism of nuclear shieldings within the four-component (Dirac) scheme.^{25,57,58} This work and its future importance was subsequently reviewed by Jameson.⁵⁹ We also refer the reader to subsequent articles by Jameson and Jameson et al. who review the literature in the computational NMR field on a yearly basis. In particular the more recent articles show a large increase of publications based on relativistic methods. See, e.g., Ref.⁶⁰ for a relativistic NMR application in solid-state physics. Already anticipated by Pyykkö⁵⁷ in his remark “A rigorous implementation of the present theory will [...] probably take some time”, four-component ab initio (Hartree–Fock) calculations of NMR shieldings in molecules have been reported only rather recently.^{26,28,31}

Following the historical computational development we discuss SO effects on NMR shieldings prior to scalar relativistic effects.

3.1 Spin-orbit Coupling Effects

The proton chemical shift in the series of hydrogen halides HX (X = F, Cl, Br, I) and the ^{13}C shifts in CH_3X are probably the most thoroughly studied parameters in heavy atom NMR computations. The reason is that these molecules are among the smallest samples in which the strong SO dependence of NMR chemical shifts can be computed and compared to experiment. The HX and CH_3X series therefore serve as benchmarks for heavy atom NMR computations where, due to the smallness of the systems, high quality basis sets can be employed nowadays. The trend being obtained from the computations is always similar, regardless of which method has been used: excluding SO coupling does not recover the experimentally observed trend, but with inclusion of SO effects the calculated values follow the experimental trend. The numerical quality of the results is, of course, much dependent on the chosen method, and also somewhat on whether scalar relativistic effects have been additionally considered or not. Table 1 displays some of the results for the HX series that have been obtained during the last three decades. The data establish that the experimental trend can indeed be explained on the basis of SO effects only, while exclusion of SO effects does not reproduce the right trend even if scalar relativistic effects are considered.

Explanations of the SO contribution to nuclear shielding have been given in almost all of the articles quoted in Table 1 and many other papers. Qualitatively, let us consider the singlet (closed shell) ground state wavefunction without SO coupling first. As in equation (18), we assume that Ψ_0 and all the excited states of the Hamiltonian (without SO coupling) are available as a complete basis set. Expanding the spin-orbit coupled wavefunction on this basis means that, due to the nature of the SO operator, contributions also from excited triplet states will enter the SO wavefunction. Now the perturbed SO wavefunction in an external magnetic field, represented in the same basis, will have different coefficients for the singlet and

triplet states and thereby the magnetic field can effectively induce a net spin density in the electronic system. The FC and SD operators also induce spin density and therefore the contribution from these operators to the NMR shielding are no longer zero.

In the case of the shielding of a light nucleus L in the neighborhood of a heavy atom Y, the spin density is induced by the external field around Y, transferred through the chemical bond(s) to the light nucleus L, and is there 'detected' by the FC and SD perturbations (heavy-atom effect on the light-atom shielding (HALA) in contrast to the heavy atom effect on the heavy nucleus shielding itself, HAAA⁶¹). This suggests a qualitative similarity to the nonrelativistic FC/SD mechanism of nuclear spin-spin coupling, where the spin density is not induced by the external field but by the FC and SD perturbation from another nucleus. This similarity has already been proposed in 1969 by Nakagawa et al.,⁵⁶ but no unambiguous numerical evidence could be provided. Recent DFT computations⁶² on a number of systems convincingly demonstrate the correlation between $K(\text{L}, \text{Y})$ and the spin-orbit contribution to $\sigma(\text{L})$ induced by Y. In particular, a familiar Karplus-type dihedral angle relation known for three-bond spin-spin couplings has been obtained for the SO contribution to proton shielding in iodoethane that closely follows the behavior of $^3K(\text{H}, \text{I})$. Many numerical results obtained by different authors show that the SD contribution to spin-orbit induced shielding can often be neglected, and the FC part is usually dominant. The same holds for nuclear spin-spin couplings (Section 4). Similar to spin-spin couplings, too, is that the magnitude of the FC contribution to nuclear shielding depends on the σ -character of the L-Y bond(s). This allows for similar chemical interpretations.^{51,62}

The case of $\delta(^{13}\text{C})$ in methyl halides is not as spectacular as the hydrogen halides. Still, qualitative agreement with experimental data can only be achieved upon inclusion of SO coupling in the shieldings calculation, while scalar relativistic corrections are of minor importance. Benchmark data for

these and other small molecules have been published, e.g., in Refs.^{32,36,43,47,49,53,63}

The importance of the influence of two-electron ($2e^-$) SO operators or the Breit correction in the Dirac scheme has been investigated by some authors.^{30,36,50} For $\sigma(^1\text{H})$ in HX and $\sigma(^{13}\text{C})$ in MeX , the $2e^-$ -SO contributions were found to be small and of opposite sign to the $1e^-$ -SO shielding terms. The relative importance of the two-electron terms appears to be generally decreasing for these cases as the heavy atom becomes heavier, contributing about 30% to the (small) SO shift caused by F substituents and about 7% to the (large) SO shift caused by iodine substituents. Similar conclusions for the relative importance of the $2e^-$ -SO terms were obtained for the shielding of the heavy atom,³⁶ for which (see next section) the scalar relativistic effects should not be neglected. For increasingly heavy X, the scalar relativistic corrections may be of higher importance than the two-electron SO terms. See, e.g., the DK results in Table 1. On the other hand, the vPSC DFT values of Ref.⁵² do not indicate such large scalar relativistic corrections. At the present level of accuracy that can currently be achieved by either nonrelativistic + pPSO or four component ab initio methods, or relativistic DFT, the two-electron SO contributions appear to be rather negligible for heavy element molecules.

One of the major successes of relativistic NMR shieldings computations has been the explanation of the origin of the 'normal' and 'inverse' halogen dependence (NHD and IHD) in many compounds. Well known to experimentalists and theoreticians, shieldings of light atoms L bound to a halogen X quite often strongly increase as X becomes heavier (NHD) and its electronegativity decreases. Examples are HX , shown above, CH_3X , CH_2X_2 , etc., and many other main group compounds in particular in high oxidation states. However, counter examples are known, where the L nucleus becomes less shielded for decreasing electronegativity (and increasing nuclear charge) of X, at least for Cl (sometimes Br) compared to F. Sometimes, in those compounds the NHD is observed again for $\text{X} = \text{I}$ (and sometimes Br). Examples are SiX_4 , AlX_4^- , and many transition metal compounds. As in HX (Table 1), in the investigated cases the NHD is caused by the

SO contribution to nuclear shielding, while the nonrelativistic computations predict an IHD behavior. Figure 1 displays the Hartree–Fock data obtained for some silicon halides in 1995. Very similar results for these and other compounds were obtained in the same year by a semiempirical approach.⁴⁴

Extremely large SO corrections to the phosphorus chemical shift in PX_4^+ have been reported in Ref.⁶⁴ and were attributed to the pronounced s-character of the L–X bonds due to the high oxidation state of phosphorus. Similar NHD results can be found in many theoretical studies of the SO shielding contribution. The authors of Ref.⁶⁵ investigated a number of Ti tetrahalides and Nb hexahalides. Rather typical for early transition metal halides, almost vanishing net SO effects on the metal shielding were observed even for the tetra- and hexa-iodides, caused by a cancellation of positive SO contributions from the FC term and negative changes of the paramagnetic shielding at the presence of SO coupling. In this case, IHD for the series $\text{F} \rightarrow \text{I}$ is observed for the chemical shifts in agreement with experiment. This has been interpreted in terms of the different nature of the metal d-orbitals binding to the ligands as compared to (s- and) p-orbitals in the case of main group elements exhibiting NHD.

If one bases the interpretation for the IHD on equation (20), the decreasing HOMO–LUMO gap due to decreasing electronegativity of the halogen in the series $\text{X} = \text{F} \rightarrow \text{I}$ results in a larger magnitude of the paramagnetic shielding, if the matrix elements in the sum over excited states are assumed to be approximately constant. (In Ref.⁶⁶, excellent linear correlation of ^{95}Mo chemical shifts with the lowest magnetically allowed d–d* excitation energy has been observed for a number of Mo complexes.) Since the nonrelativistic paramagnetic shielding contribution is typically negative, this results in increasingly positive chemical shifts (IHD). From the investigations quoted above it becomes clear that the NHD, on the other hand, is due to the more pronounced influence of spin-orbit coupling, which often increases the shielding and therefore causes increasingly negative chemical shifts. The diamagnetic shielding, as a core property, is usually found to be of small influence concerning the chemical shifts. From the relativistic nature of the NHD it becomes clear why previous

Figure 1 ^{19}Si chemical shifts with respect to SiF_4 in silane and some silicon halides, from Hartree–Fock data.³³ Scalar rel. and SO effects considered here via ECPs on the halide ligands. (a) experimental vs. computed Si shifts. (b) NHD and IHD along the SiX_4 series. See Section 3.1

explanations of the NHD that only take the (nonrelativistic) paramagnetic shielding into account have not generally been convincing.

Density functional theory (DFT) has been particularly successful in the case of transition metal compounds, and generally in cases for which electron correlation has a strong influence on the NMR shielding, and where a correlated *ab initio* method including relativistic effects has not been available or has not been applicable due to the size of the system (see also the section on spin–spin couplings). An example where electron correlation is believed to be very important is the ^{13}C shift in the series of CX_3^+ . Nonrelativistic DFT and MP2 calculations show very similar results exhibiting IHD. This trend is also observed, but strongly overestimated, by nonrelativistic Hartree–Fock calculations, indicating the importance of electron correlation. Further inclusion of SO coupling in the DFT calculations recovers the experimentally observed NHD for $\text{X} = \text{Cl} \rightarrow \text{Br} \rightarrow \text{I}$ with good accuracy.⁶⁷

Most of the relativistic DFT studies of transition metal compounds include scalar relativistic effects and are discussed in the next section.

3.2 Including Scalar Relativistic Effects

From a computational point of view, the most simple way of including scalar relativistic effects in a NMR shieldings calculation is to use an available scalar relativistic ECP on the heavy atom. When HALA effects are studied, existing nonrelativistic NMR code can be (and is) used without modifications. Many studies have been carried out using this approach, see, e.g., Refs.^{51,68} for overviews of density functional applications in particular to transition metal complexes. In view of the importance of SO corrections to σ as seen in the previous section, however, the range of applications of this method seems to be limited. Spin-orbit ECPs have been applied to a number of NMR ligand shieldings including heavy main group and transition metal compounds.^{33,63} Restrictions with respect to HALA effects also apply to the purely scalar relativistic approach of Ref.⁵², in which HX and a number of transition metal complexes are studied. However, the method is capable of treating the heavy metal shift (and HAH effects) itself, with reasonable accuracy as shown for the W shifts in Table 2. In Ref.⁶⁹, an overview of this variational scalar Pauli method is given. Among other data, a large number of ^{125}Te shifts are presented. In comparison with experiment, the relativistic computations achieved good accuracy, therefore SO effects can be regarded as mostly unimportant for Te chemical shifts. An increase of the scalar relativistic effects of the shielding of the heavy nucleus X with $\sim Z^{3.5}$ has been found from SCDK calculations for the HX series.²¹ This underlines the importance of scalar relativistic corrections for heavy

nucleus shieldings. Computational methods that include both scalar relativistic and SO effects and have been applied to both light and heavy nucleus shieldings are, of course, the four-component methods,^{26,28,30} and, e.g., Douglas–Kroll including SO effects,^{70–72} Pauli including SO,^{22,53} or the ZORA approach.^{19,73} A collection of transition metal tetroxo- and hexacarbonyl complexes appears to represent a benchmark test set for DFT NMR implementations. Oxygen shifts of group 6–8 transition metal tetroxo-complexes were studied, e.g., in Refs.^{52,74} with a scalar relativistic approach. The rather good agreement with experimental shifts suggests that SO coupling does not play an important role in this case. Scalar relativistic effects on the ligand shifts appeared to be of high importance only for the 5d metals and are almost negligible for the 3d metals. The metal shifts in the same set of complexes were studied by variational scalar + SO Pauli and ZORA SO DFT.⁷⁵ Unfortunately, no oxygen shifts were reported there for comparison. The results for the metal shifts have been satisfactory, with ZORA emerging as the superior method in this case. Table 2 displays some ^{183}W shifts that were obtained by DFT methods and by a Hartree–Fock approach⁷⁰ including scalar + SO effects. The results indicate that scalar and SO effects are probably of equal importance for the W shifts. In Ref.⁷⁶, a larger number of W shifts than quoted in Table 2 have been computed by both vPauli and by ZORA DFT. ZORA resulted in a mean error of approximately 3% of the total shift range of 7000 ppm for the investigated samples when compared to experiment. The Pauli approach performed worse in this case, with an error of about 6%. ZORA produced a similar accuracy for a number of ^{207}Pb chemical shifts reported in the same study (4% error compared to the covered shift range), whereas the mean error from the Pauli approach was found to be four times larger in this case. The ZORA computations predicted an enormous SO shift of the Pb shielding of PbI_4 of more than -8000 ppm, a number yet to be supported by experimental results.

Carbon chemical shifts for 5d transition metal carbonyl complexes studied with DFT are displayed in Table 3. SO effects play a less significant role for the ^{13}C chemical shift in these complexes as compared to HX, but systematically improve the computed results. The SO shifts do not easily follow intuitive arguments based on the size of the HOMO–LUMO gap (HLG).⁵³ From equation (20) the individual contributions to the shielding can be expected to decrease with increasing HLG along a row of the periodic table. Despite the fact that the HLG increases from approximately 2 to 6 eV from $[\text{Hf}(\text{CO})_6]^{2-}$ to $[\text{Ir}(\text{CO})_6]^{3+}$, the spin-orbit contribution to the nuclear shielding and to the chemical shift is nevertheless seen to be increasing from Hf to Ir. As illustrated in Ref.⁵³, the trend can be rationalized on the basis that, due to the relative energies of the metal d_σ , d_π and the CO σ and π^*

orbitals, the bonding in Hf carbonyl is dominated by $d_{\pi}-\pi_{\text{CO}}^*$ interaction, whereas the bonding in Ir carbonyl is dominated by $d_{\sigma}-\sigma_{\text{CO}}$ interaction. CO is more likely to σ -donate charge to the highly positively charged Ir, whereas metal-ligand π -back-donation dominates in the Hf complex. Only in the former case, however, can spin density be effectively transferred to the carbon nucleus, therefore the magnitude of the SO induced carbon shift is increasing along the 5d transition metal carbonyl series despite the increasing HLG. It has been shown previously that the decreasing $\delta(^{13}\text{C})$ along the series at the scalar relativistic level is due to a complex interplay of different factors in which the amount of π -back-donation is predominant.^{77,78}

In a ZORA DFT study of ^{195}Pt chemical shifts,⁷⁹ the authors also found that simple arguments based on the magnitude of $1/(\epsilon_i - \epsilon_a)$ are not always able to provide an explanation of the observed trends. The magnitude of the matrix elements in the numerator of the sum in equation (20) has to be considered as well and needs to be explained by intuitive chemical arguments. In the case of Pt shifts, NHD is observed in many cases. An analysis of the computational data shows that both the SO contributions and the paramagnetic shielding approximately equally contribute to the NHD. For the paramagnetic Pt shielding, this was attributed to a preference of the soft acid Pt(II) to bind to the soft base I instead of Cl. The authors in Ref.⁷⁹ could numerically and graphically illustrate that this results in a smaller magnitude of the (negative) paramagnetic shielding for iodine ligands due to smaller paramagnetic matrix elements in equation (20) that overcompensate the opposite HLG influence. The overall accuracy of the ZORA DFT method for Pt shieldings resulted in a mean error of approximately 10% of the investigated chemical shift range for 23 samples.⁷⁹

Mercury shieldings have been computed by DFT and Hartree–Fock methods.^{19,71,72} Table 4 lists some results that have been obtained. As can be seen from the data for HgMeX and HgX_2 , the mercury halide compounds exhibit NHD, largely caused by the SO effects on the nuclear shieldings.^{19,71} Large ‘coupling’ between scalar and SO corrections to mercury shifts were noted in Ref.⁷¹ This means that the inclusion of both relativistic mechanisms is important in order to achieve reasonable results, because the SO correction based on a non-relativistic zeroth order solution is much different from the one obtained from a scalar relativistic one. It is well known that scalar relativistic effects substantially stabilize and contract the 6s orbital in Hg, while the Hg 5d shell is destabilized and spatially expanded as compared to nonrelativistic computations.

In effect, the scalar relativistic Hg–ligand bonds are much different from the nonrelativistic ones, meaning that the s and d contributions in the occupied and virtual metal-ligand orbitals, that determine to some extent the magnitude of the SO corrections to the chemical shifts, will be very different as well. In Ref.⁷¹, the rather unsatisfactory performance of the computations, in particular the strong overestimation of the SO shift corrections for the HgX_2 series (Table 4, large basis set) was attributed to the missing treatment of 2e-SO terms. The authors proposed that 20–40% of the 1e-SO contribution to the chemical shift may be canceled by the two-electron contributions, which seems to be excessive taking the previously quoted findings about the relative importance of the two-electron SO terms for heavy atom compounds into account. Considering the reasonable overall performance of the DFT calculations for Hg shifts (they do not include 2e-SO operators explicitly), the inaccuracies of the Hartree–Fock results for HgX_2 could also be attributed to the missing treatment of electron correlation. Another problem might be the inconsistent treatment of relativity, viz. the use of the problematic Pauli SO operator in conjunction with the scalar relativistic DK Hamiltonian. This has been criticized by Fukui.²¹

For the series $\text{Hg}(\text{LCH}_3)_2$, L = C, Si, Ge, which has been computed with a DK transformed Hamiltonian including SO coupling, it was found that the rather small magnitudes of Hg chemical shifts are caused by cancellation of large relativistic and nonrelativistic contributions.⁷² Even the usually negligible SD contribution to the chemical shift is here comparable in magnitude to the shift itself. In that respect, the achieved results must be regarded as quite accurate and testify to the accuracy of the relativistic treatment with the DK Hamiltonian. The authors also consider missing solvent effects as a possible source of error, an issue that has already been addressed regarding mercury chemical shifts.¹⁹ Experimentally confirmed, the solvent dependence of, e.g., the Hg shift in HgI_2 can amount to more than 1000 ppm (pyridine vs.

THF). It has been computationally demonstrated in Ref.¹⁹, that direct coordination of the metal by a nucleophilic solvent (pyridine, simulated by NH_3 in the ZORA computations) is largely responsible for the large experimental solvent effects on chemical shifts. The computations were able to qualitatively simulate a strong positive contribution to $\delta(^{199}\text{Hg})$ due to the coordination of the solvent to Hg. The resulting geometry change (bending of X–Hg–X by approximately 30°) upon complexation was found to increase the magnitude of the (negative) chemical shift by ~ 600 ppm for HgCl_2 , while the direct interaction of the solvent with the heavy atom caused a large shift of δ by $\sim +1100$ ppm. THF was supposed to coordinate much less strongly to Hg and not to cause a significant change of the linear structure of HgX_2 . A possible influence on the chemical shift due to THF that might account for the differences between theory and experiment in Table 4 has therefore not been investigated.

It should be noted here that absolute shielding values of, e.g., 8020 ppm from ZORA DFT,¹⁹ and of 15 128 ppm from spin-orbit DK Hartree–Fock⁷² for ^{199}Hg in $\text{Hg}(\text{CH}_3)_2$ have been reported. While the paramagnetic and diamagnetic shieldings are approximately equal in both methods, the reported spin-orbit corrections differ by ~ 7000 ppm. The differences obviously largely cancel regarding the chemical shift and demonstrate that due to cancellation of systematic errors, chemical shifts are much easier to compute accurately than absolute shieldings in particular for such heavy nuclei. We therefore do not list reported absolute shielding values in the tables.

Chemical shifts in compounds containing elements as heavy as uranium have been investigated^{73,80} with DFT. In Ref.⁸⁰, variational Pauli and ZORA calculations have been employed together with standard GGA functionals, as well as a scalar relativistic ECP in conjunction with the B3LYP hybrid functional. ^{19}F chemical shifts in a number of U-halide complexes were obtained with moderate absolute accuracy with both the ZORA and the Pauli approaches, while certain trends between different compounds could not be reproduced by the GGA functionals. SO effects for the F shifts were found to be of low importance (typically ~ 30 ppm for Pauli and somewhat less for ZORA, as compared to experimental shifts between 750 and 790 ppm). The scalar relativistic ECP/B3LYP did yield systematically between 80 and 270 ppm too large chemical shifts, but certain trends were better reproduced. From this, the authors concluded that the ECP approach is beyond its limit for actinide NMR and that improved XC functionals are needed for the nonhybrid DFT methods in order to reproduce some trends among a series of compounds more accurately. A clearly better performance of ZORA vs. Pauli could not be observed in this study.

Many of the studies cited so far also provide relativistic effects on the shielding tensor anisotropy, $\Delta\sigma$. See Refs.^{28,36,37} for examples. The practical application of these quantities for heavy atom systems is, however, rather limited so far. We therefore refer to the literature for detailed discussions of relativistic effects on $\Delta\sigma$, and only mention here that huge effects have been reported so far.

4 HEAVY ATOM SPIN–SPIN COUPLINGS

Nuclear spin–spin couplings are not very easy to compute accurately, in particular for heavy elements, but can often be

measured with high precision. Unlike the case of chemical shifts, where systematic errors in the computation may cancel when the shifts are obtained from the difference of the two computed shielding values of the probe and the reference compounds, there is no such cancellation of errors for spin–spin couplings. Another problem is that the interest is often in couplings involving a heavy nucleus itself, and scalar relativistic effects can be enormously large. Therefore, attempts to calculate spin–spin couplings similarly to the NMR shieldings case just by considering the Pauli SO operator to first order did not yield very satisfactory results for couplings involving a heavy nucleus.^{38–40} However, this method seems to be applicable for the study of HALA effects in some cases.³⁸ Likewise, ECPs can be employed for this type of application (e.g., in Ref.⁸¹). However, in the following we focus on couplings to a heavy nucleus itself. As compared to chemical shieldings, much less computational data are yet available.

4.1 (Mostly) Scalar Relativistic Effects

Scalar relativistic effects are usually believed to yield the major influence on heavy nuclear spin–spin couplings. The reason for this is related to the fact that the FC term (27e) was found to represent the dominant contribution for an overwhelming number of couplings that have been investigated (of course, counter examples are known). In its usual nonrelativistic form for point-like nuclei, the FC term originates from the value of the induced spin-density *directly* at the nuclei, while its relativistic generalizations probe the space very close to the nuclei.^{20,29} There, in particular, the electron density is substantially modified due to the scalar relativistic operators ($\text{MV} + \text{DAR}$ in the Pauli formalism, equation (11)), and a huge influence on the FC perturbations can be expected. This was noted in 1968⁸² regarding the contact term in NMR spin–spin coupling and has been known since 1930⁸³ from the theory of atomic hyperfine splittings.

The authors of Refs.^{45,46} introduced relativistic correction factors (RCFs) for hyperfine integrals of atomic orbitals (AOs), which account for the relativistic increase of the electron density at the respective nucleus. The RCFs can then be used in nonrelativistic molecular computations to scale the AO integrals entering the FC expression for the coupling tensor in equation (20). The authors of Ref.⁸⁴ reported a somewhat related procedure that is applicable to couplings involving a heavy nucleus, based on the variational scalar Pauli treatment. The semiempirical approaches described in, e.g., Refs.^{85–88} also make use of integrals based on four-component atomic computations in an otherwise nonrelativistic formalism.

To give the reader an idea of the magnitude of the RCFs, we note that, e.g., a value of 2.4386 has been reported⁴⁵ for the Hg 6s orbital. This means that, if the coupling Hg–L (L = light nucleus) is dominated, as it is often the case, by the FC contribution and by the 6s orbital on the Hg side, the coupling relativistically increases by almost a factor of 3. Likewise, Hg–Hg and other couplings between 6th row elements can be expected to relativistically increase by almost an order of magnitude. Even for rather light fourth row nuclei, nonnegligible relativistic effects on coupling constants of $\sim 10\%$ can be expected. This should be compared to the celebrated huge relativistic bond contraction of many Au(I) compounds, which is of the order of 10%.

A problem connected with the RCFs is that they do not account for relativistic changes of the molecular orbitals that determine the spin–spin coupling. Such changes would be obtained from a variational or higher than first-order perturbational relativistic molecular computation. The RCFs are also not able to describe relativistic effects of L–L' couplings in the neighborhood of a heavy nucleus for the same reason. In many cases, relativistic changes of the zeroth-order solution may either enhance or quench the strong relativistic effects of the AO integrals and lead to much different answers than obtained from the RCFs. In these, and other cases for which the coupling is not dominated by the FC term, a consistent first-principles variational or perturbational scheme for molecules is desirable.

The four-component formalism of nuclear spin–spin couplings has been subsequently published by Pyykkö, who provided a simple LCAO example for $K(\text{Hg}-\text{C})$ in dimethylmercury.⁸⁹ The results are very typical for heavy-atom spin–spin couplings. They exhibit a huge relativistic increase of $K(\text{Hg}-\text{C})$ by a factor of 2.7, with the new mixed contributions due to spin-orbit coupling being almost negligible for the isotropic coupling and yielding a somewhat larger contribution to the anisotropy ΔK of the coupling tensor. ΔK thereby increased even stronger by a factor of 3.3 due to relativity. A formulation for spin–spin couplings within the four-component scheme based on the polarization propagator method has been published by Aucar and Oddershede.⁹⁰ An implementation for spin–spin couplings within the relativistic extended Hückel theory (REX) was applied to many systems and often recovered the experimentally observed trends and provided explanations.⁹¹ Recently, an ab initio Hartree–Fock four-component implementation and benchmark results for HX , H_2Y , ($\text{Y} = \text{O}, \text{S}, \text{Se}, \text{Te}$), and some plumbanes have been reported.^{24,28,29} Also rather recently, the two-component ZORA DFT approach for spin–spin couplings has been formulated and implemented by the present authors.^{20,54} Earlier semiempirical approaches based on the MNDO, AM1 and PM3 Hamiltonians, and ab initio methods including the Pauli SO operator, have already been mentioned. See Ref.²³ for a review on hyperfine interaction in metals from the solid-state physics point of view.

The series YH_4 , $\text{Y} = \text{C}, \text{Si}, \text{Ge}, \text{Sn}, \text{Pb}$, has been studied as benchmark systems in many of the references cited so far. The results show a strong scalar relativistic increase in the FC contribution to the Y–H coupling, that amounts to roughly a factor of two in the case of $\text{Y} = \text{Pb}$. Table 5 displays spin–spin couplings in plumbanes obtained from different theoretical methods. Nonrelativistically, the FC term to the couplings is dominant and all other contributions are almost negligible. In the relativistic case, the situation is not much different. The new mixed contributions due to SO coupling are not negligible, but rather small.^{40,54,91} The scalar relativistic corrections to FC terms of the Pb–L couplings clearly dominate and it can be seen from Table 5 that the total relativistic corrections to the Pb–L couplings are very substantial. The correlated ab initio study of Kirpekar et al.,⁴⁰ only including SO effects, was not able to achieve qualitative agreement with experiment, but could provide evidence that SO effects on $K(\text{Pb}-\text{H})$ in PbH_4 are indeed not very large (and negative in this case). The largest SO contribution is due here to the OP-FC cross term (which is zero in the nonrelativistic limit).^{40,54} Therefore, large SO effects on the coupling constants can be expected only for those systems where SO coupling is of high importance (typically heavy p-block elements such as Tl, Bi, Pb), and both the FC and the paramagnetic coupling contribution are not very small already at the non- or scalar-relativistic limit. This is not the case for the plumbanes, and therefore the scalar relativistic effects on the FC term dominate the picture. This also rationalizes the quite accurate results for PbH_4 and PbMe_4 in Refs.^{84,86} Compared to other studies of sixth row element one-bond couplings, the data in Table 5 appear to be rather typical and qualitatively similar results have been, e.g., obtained for couplings involving W, Pt and Hg in a number of heavy metal complexes.^{20,84} As for the plumbanes in Table 5, chemical trends for very similar compounds are often already reproduced at the nonrelativistic level while magnitudes of coupling constants typically increase by a factor of two due to scalar relativistic corrections. Already at the scalar relativistic level, good agreement with experiment has been achieved for most of the systems in Refs.^{20,84}.

From the data in Table 5, the importance of electron correlation for obtaining reasonable estimates of spin–spin coupling constants becomes obvious. The effect of correlation

at the nonrelativistic *ab initio* level is seen from a comparison of the *nrel.* number in parentheses listed for the Dirac approach with the one from the MCSCF computation. Based on a respective nonrelativistic ratio for SiH_4 , Enevoldsen et al.²⁹ estimated a Pb–H coupling constant in PbH_4 of $\sim 138 \times 10^{20} \text{ kg m}^{-2} \text{ s}^{-2} \text{ A}^{-2}$ for a correlated approach. This is very close to the ZORA DFT result and underlines on the one hand the sensitivity of spin–spin coupling constants with respect to the quality of the zeroth-order solution and on the other hand the fact that standard DFT functionals partially account for the influence of correlation. The semiempirical methods try to incorporate these effects via their parametrization. As seen from Table 5, the results for PbH_4 and PbMe_4 are in rather good agreement with experiment. However, the Pb–Cl coupling in PbCl_4 appears to be strongly underestimated by the AM1 method. The authors list a better coupling constant of $-80.6 \times 10^{20} \text{ kg m}^{-2} \text{ s}^{-2} \text{ A}^{-2}$ obtained with the PM3 semiempirical Hamiltonian in Ref.⁸⁶, but on the other hand $K(\text{Pb–H})$ in PbH_4 is overestimated by more than a factor of five with PM3. In a comparison of theory and experiment for the YCl_4 series, $\text{Y} = \text{C, Si, Sn, Pb}$, the semiempirical methods systematically underestimate the magnitude of the Y–Cl coupling constant, with the PM3 results being substantially larger than the AM1 (and MNDO) results. REX performs rather well in comparison.⁹¹ The strong overestimation of some coupling constants in the semiempirical methods has been attributed to the ‘triplet instability’ problem that also plagues the Hartree–Fock approaches.¹² The DFT methods seem to be much more robust in this case. Both scalar and SO ZORA DFT have predicted a negative Pb–C coupling constant for PbMe_4 despite the fact that the nonrelativistic limit, other computations, and the quoted experimental coupling (from 1978) agree on a positive value. In all other cases we have investigated so far, ZORA did yield the experimentally predicted sign of K and in most cases the magnitudes were reproduced with good accuracy.

As already mentioned in Section 3, solvent effects can substantially influence NMR parameters for heavy atom compounds. In particular, it was found that complexation of the heavy atom by solvent molecules, if possible, yields huge effects on shieldings of the heavy nucleus. It is therefore not very surprising that this is the case for NMR spin–spin couplings as well. More surprising, however, is the magnitude of the effects even for rather weakly coordinating solvents that do not cause a significant change in the geometry of the compound under investigation. In Ref.⁹², a number of linear mercury and square-planar platinum complexes have been investigated. Even for such weakly coordinating solvents such as CHCl_3 or CH_2Cl_2 , a significant shift of the FC contribution to the spin–spin coupling has been observed. Experimental trends for different solvents (CHCl_3 vs. DMSO) have been quantitatively reproduced. The solvent coordination effect has been analyzed in detail for $\text{Hg}(\text{CN})_2$. $K(\text{Hg–C})$ increases from 237.9 to 443.4 to $576.2 \times 10^{20} \text{ kg m}^{-2} \text{ s}^{-2} \text{ A}^{-2}$ at the nonrelativistic, scalar ZORA relativistic, scalar rel. + $4\text{CH}_3\text{OH}$ solvent molecules level, respectively (DFT, VWN functional). SO corrections were small in the samples studied in Ref.⁹² It was found that charge donation from the solvent into the metal–ligand σ bonds is responsible for the large positive shift of $K(\text{Hg–C})$. It does not seem very likely that unspecific solvent effects for coordinatively saturated complexes are of such high importance, but

they will be not negligible for high-accuracy computations. In Ref.⁹³, complexation of the complex $[(\text{NC})_5\text{Pt–Tl}(\text{CN})]^-$ by water was found to explain a rather unintuitive experimental result for the Tl–C couplings. In aqueous solution, $^2K(\text{Tl–C}) \gg ^1K(\text{Tl–C})$ has been observed experimentally. In the same complex, the huge Pt–Tl coupling (expt. $\sim 57 \text{ kHz}$ in water) has been shown to increase by more than 20 kHz upon coordination by solvent molecules in the ZORA DFT computations.

4.2 Spin-orbit Effects

Not many cases have been investigated so far, where SO coupling is of essential importance for heavy nucleus spin–spin coupling constants. Very often it is possible to achieve a good comparison between theory and experiment at the computationally much cheaper and easier to interpret scalar relativistic level. As a counter example, we would like to emphasize the case of Tl halides, TlX.

Figure 2 shows the coupling constants that have been obtained with the ZORA DFT approach⁵⁴ on different levels of approximation. Clearly, SO effects yield the dominant contribution to the coupling constants for TlI and a completely wrong trend for the series is obtained at the scalar relativistic level. The explanation for the SO effects follows that for the chemical shieldings. Mixed terms between the spin-dependent FC and SD operators and the orbital dependent OP operator are no longer zero in the presence of SO coupling. Through SO coupling, the spin-density that is induced by the FC perturbation at a nucleus ‘leaks’ through into the orbital shapes and causes orbital current densities that yield nonzero coupling contributions with the orbital currents induced by the OP term at the other nucleus. Likewise, the OP operator induces spin-density in the SO coupled system. As for nuclear shieldings, the FC–OP cross term was found to be dominant and the SD–OP term small.^{39,40,54} For TlX, the paramagnetic contribution is dominant at the nonrelativistic level and the FC term represents

Figure 2 Reduced spin–spin coupling constants in thallium halides TlX from ZORA DFT computations (Ref.⁵⁴, BP86 functional), in $10^{20} \text{ kg m}^{-2} \text{ s}^{-2} \text{ A}^{-2}$. Calculated vs. experimental values. Experimental data compiled in Ref.⁹⁴

the second largest contribution. This leads to the large FC-OP cross terms at the SO coupled level. In the case of TII, this cross term represents the largest individual relativistic correction to the coupling constant and is essential in order to obtain the correct trend for the TIX series.⁵⁴ The DFT approach appears to be of somewhat reduced accuracy for the case of TIBr and TII which has been largely attributed to deficiencies in the GGA functional.⁵⁴

The authors of Ref.³⁸ concluded from a study of $K(\text{H}-\text{H})$ in H_2Y ($\text{Y} = \text{O}, \text{S}, \text{Se}, \text{Te}$) that the SO effects may generally yield the dominant contribution for HALA effects as is the case for many nuclear shieldings. A large relativistic change of $K(\text{H}-\text{H})$ in PbH_4 has been observed from four-component Hartree-Fock computations²⁹ where SO effects are naturally present. On the other hand, Ref.⁴⁰ reports rather small SO corrections to $K(\text{H}-\text{H})$ in PbH_4 , based on a nonrelativistic Hartree-Fock wavefunction. Furthermore, huge changes of the FC term due to electron correlation were found. Clearly, more relativistic studies including both scalar and SO effects are needed in this case in order to draw a definite conclusion.

Available studies have shown that even in those cases where the SO effect on the coupling constant is rather small, the anisotropy ΔK can be quite strongly influenced by SO coupling. Relativistic changes of ΔK have been reported in several of the papers cited so far, e.g., in Refs.^{24,28,38,54,87,91} However, the applications of ΔK for the heavy atom case are, as in the $\Delta\sigma$ case, very limited so far. It is already established that future investigations of ΔK and interpretations of respective experimental findings will need to include relativistic effects if heavy atom systems are studied, and both scalar and SO effects will be of importance in this case. Experimental data for the TIX series have, along with a number of other light and heavy diatomic systems, been investigated in Ref.⁹⁴ and periodic trends of K and ΔK have been analyzed. ΔK can generally be expected to increase with increasing charge of the heavy nuclei involved, with very large anisotropies for couplings with sixth row atoms in particular at the right end of the periodic table.

5 SUMMARY

It is nowadays possible to compute relativistic heavy nucleus NMR parameters by a variety of different approaches at different levels of accuracy and computational expense. A number of available quantum chemical program systems are capable of such computations. From the numerical evidence provided so far by many computational studies of NMR parameters in heavy atom systems, it becomes obvious that relativistic effects can be responsible for the main chemical trends that have been observed experimentally. In particular, spin-orbit coupling must be considered for shieldings of light nuclei in the neighborhood of heavy p-block elements. Both scalar and spin-orbit relativistic corrections are important for shielding tensors of heavy nuclei and ligand shieldings in heavy transition metal complexes. It is imperative to use scalar relativistic corrections in order to compute reliable magnitudes for spin-spin couplings involving heavy nuclei. Spin-orbit corrections to spin-spin couplings can be very substantial if both the paramagnetic and the Fermi-contact contributions

to the coupling are large and a heavy p-block element is involved.

Biographical Sketches

Jochen Autschbach, *b* 1968. M.Sc. (Chemistry), 1996, Ph.D., 1999, Siegen, Germany. Ph.D. thesis on relativistic effects in atoms and chemical bonds. Since 1999 member of Tom Ziegler's research group in Calgary, Canada. Current research interests: computation of heavy atom NMR spin-spin coupling constants and chemical shifts, solvent effects in spectroscopy, theory of optical activity, density functional response theory, relativistic quantum chemistry. J. A.

has contributed, among other code, a program for the computation of heavy atom spin-spin couplings to the Amsterdam Density Functional program.

Tom Ziegler, *b* 1944. T. Z. was raised in Denmark and graduated from the University of Copenhagen in 1972 with a Cand. Scient. degree in theoretical chemistry. He obtained a Ph.D. from University of Calgary (1978) where he has been a full professor since 1991. He has in the last 25 years worked with the development of density functional theory as a practical tool in transition metal chemistry and homogeneous catalysis. This has led to computational methods of use in spectroscopy, thermochemistry, structure determination and molecular dynamics. He is a fellow of both the Royal Danish and Royal Canadian Societies.

Relaxation of Transverse Magnetization for Coupled Spins

1 INTRODUCTION

Several excellent articles on Redfield relaxation theory are presented elsewhere in this Encyclopedia (see, e.g., **Relaxation Theory: Density Matrix Formulation**), and the applications given here are based on that work. The theory is not only simple and elegant, it is also a very powerful and useful tool for the experimental NMR spectroscopist. As shown below, NMR relaxation time measurements of coupled spin systems provide a wealth of information about molecular structure and molecular dynamics in solution that is available in no other way. Such studies are especially important, since a large fraction of chemistry takes place in solution or at interfaces where molecules are still mobile.

For an isolated spin system consisting of two spins of $\frac{1}{2}$ (e.g., C–H, P–H, C–F, P–F, etc.) at low magnetic fields (2.3 T or lower) where only dipolar relaxation is important, the NMR relaxation in a nonviscous fluid sample can be characterized by a single parameter, R_1 , the spin–lattice relaxation rate, since in this case the longitudinal relaxation, R_1 , and the transverse relaxation, R_2 , are equal. That is, all four spectral lines (two for each nucleus) have the same relaxation rate. For magnetic fields of 4.7 T (200 MHz for protons) and higher, most nuclei other than hydrogen are relaxed by both the dipolar and by the chemical shift anisotropy (CSA) mechanisms. In this event, for a coupled system, the observed relaxation rate cannot be described as the sum of the relaxation rates of the contributing mechanisms, that is, $R_{\text{total}} \neq R_{\text{dipolar}} + R_{\text{CSA}}$. Furthermore, four parameters are required to describe the transverse relaxation (each of the four lines has a different R_2 value);^{1–9} and for longitudinal relaxation, each line relaxes as a triple exponential.^{6–12}

A clear understanding of such relaxation processes is essential, since it has recently been shown that in coherence transfer experiments on large molecules (with long correlation times), anomalous peaks may arise in 2D multiple quantum filtered correlation spectra owing to the presence of such multiple relaxation processes.¹⁰ Differential relaxation can also affect two-dimensional correlation (COSY) experiments.^{13,14}

The experiments in an aqueous solution of Na₂PHO₃ discussed below provide insight into these differential longitudinal and transverse relaxation processes.

For the general case of two coupled spins of $\frac{1}{2}$, A and K, the parameters that affect the longitudinal and the transverse relaxation are the CSA values of spin A and spin K, the A–K bond distance, the molecular correlation time, and the random field terms. The simultaneous determination of all these parameters at a given temperature presents the opportunity to measure their temperature dependence, a situation that is not possible when relaxation is due to a single relaxation mechanism¹⁵ or when one of the two spins is decoupled. In addition, in the coupled experiments described here, the temperature dependence of the random field terms provides information about the molecular motion of those solvent molecules that are in close proximity to the spin pair.

2 REDFIELD THEORY AND TRANSVERSE RELAXATION

The theory of spin–lattice relaxation in coupled spin systems has been treated thoroughly by a number of authors,^{1–12} and is not repeated in detail here. For the most general case, the time evolution of the density matrix σ is given by

$$\frac{d\sigma}{dt} = \mathbf{R}[\sigma - \sigma(\infty)] \quad (1)$$

This equation can in most cases be greatly simplified. If the basis functions for the density matrix are eigenstates of the Hamiltonian then the diagonal elements σ_{ii} of the density matrix represent the populations of the energy levels, and are related to the longitudinal (T_1) relaxation. Furthermore, in this eigenbasis representation, if the eigenstates are not degenerate, the density matrix elements σ_{ij} are not connected via the relaxation superoperator to any other matrix elements, and the time evolution of these states is given by

$$\frac{d\sigma_{ij}}{dt} = -R_{ijij}[\sigma_{ij} - \sigma_{ij}(\infty)] \quad (2)$$

Given the boundary condition that the transverse magnetization at time $t = 0$ is $\sigma_{ij}(\text{max})$, the solution of the above differential equation is

$$\sigma_{ij}(t) = \sigma_{ij}(\text{max}) \exp(-t/T_2) \quad (3)$$

Equation (3) tells us that the free induction decay (FID) signal for the coherence σ_{ij} will decay as a single exponential with a time constant T_2 . The Fourier transform of this FID is consequently a Lorentzian line with a linewidth, $\pi \Delta\nu_{1/2}(i \rightarrow j) = R_{ijij}$ (see Figure 1). The matrix elements R_{ijij} are then related in a simple fashion to the linewidths of the six transverse coherences for the two-spin system. There are four single quantum coherences: R_{1212} and R_{3434} , the low- and high-frequency lines, respectively, in the carbon spectrum (for a carbon–hydrogen spin pair), and R_{1313} and R_{2424} , the low- and high-frequency lines, respectively, in the proton spectrum (a similar situation would hold, of course, for a proton–phosphorus spin pair or a fluorine–phosphorus spin

Figure 1 The energy level diagram for PHO_3^{2-} . The labeled wavefunctions correspond to the weak coupling limit. The transitions are as follows: $1 \rightarrow 3$ and $2 \rightarrow 4$ correspond to the low- and high-frequency proton peaks, $1 \rightarrow 2$ and $3 \rightarrow 4$ correspond to the low- and high-frequency phosphorus peaks, $2 \rightarrow 3$ corresponds to the zero quantum transition, and $1 \rightarrow 4$ corresponds to the double quantum transition

pair). We may indirectly measure the zero quantum coherence rate constant R_{2323} and the double quantum coherence rate constant R_{1414} . These relaxation matrix elements are related in a straightforward fashion to the dipolar parameter p , the two chemical shift anisotropies $\Delta\sigma_I = \delta_I$ and $\Delta\sigma_S = \delta_S$, the molecular correlation time, τ_c , and random field terms as indicated in Table 1.

This is, in principle, an attractive way to obtain a wealth of information about molecular structure and molecular dynamics, since it would appear that one need only measure six relaxation rates. As mentioned above, in a completely homogeneous magnetic field, the rate constant is related to the spectral linewidth:

$$R_{ijij} = (1/T_2)_{(i \rightarrow j)} = \pi \Delta\nu_{1/2}(i \rightarrow j) \quad (4)$$

where $\Delta\nu_{1/2}(i \rightarrow j)$ is the full width at halfheight of a peak with Lorentzian lineshape.

In practice, accurate values of the transverse relaxation time may be obtained using the experimental linewidth only when the relaxation time is short. In this event, the linewidth is usually very large compared with any magnetic field inhomogeneities. In principle, accurate values for the linewidth may be obtained by a spin echo experiment, which circumvents the errors arising from pulse imperfections and self-diffusion through an inhomogeneous field. One popular and often used version of the spin echo experiment is the one proposed by Meiboom and Gill.¹⁶ This experiment uses the pulse sequence

$$90_x^\circ - (\tau - 180_y^\circ - \tau)_n \quad (5)$$

This is a variation of the Carr–Purcell pulse sequence.¹⁷ This experiment is, in principle, quite straightforward. In practice, it is very difficult to obtain accurate, meaningful results in the laboratory. If done with great care, however, this experiment is capable of providing accurate results. Vold et al.¹⁸ used numerical analysis of the Bloch equations to evaluate the effects of several experimental conditions. To obtain an accuracy of 1–2% in CPMG experiments, they suggested that the following conditions be satisfied.

Table 1 Relaxation Matrix Elements for a Weakly Coupled System of Two Spins of $\frac{1}{2}$ in the Population Basis; the Y_{ijij} and Z_{ijij} Random Field Terms Include the Longitudinal Random Field Terms A and B

Longitudinal	
$R_{1111} = -3(p - \delta_I)^2 k_I - 3(p - \delta_S)^2 k_S - 12p^2 k_+ - \frac{1}{2}(A + B)$	
$R_{1122} = 3(p - \delta_S)^2 k_S + \frac{1}{2}A$

$R_{2233} = 2p^2 k_-$	
$R_{2244} = 3(p + \delta_I)^2 k_I + \frac{1}{2}B$	
$R_{3333} = -3(p - \delta_I)^2 k_I - 3(p + \delta_S)^2 k_S - 2p^2 k_- - \frac{1}{2}(A + B)$	
$R_{3344} = 3(p + \delta_S)^2 k_S + \frac{1}{2}A$	
$R_{4444} = -3(p + \delta_I)^2 k_I - 3(p + \delta_S)^2 k_S - 12p^2 k_+ - \frac{1}{2}(A + B)$	
Transverse	
$R_{1212} = -3(p^2 + \delta_I^2) k_I - 3(p - \delta_S)^2 k_S - 4(p - \delta_S)^2 k_0 - 6p^2 k_+ - p^2 k_- - Y_{1212}$	
$R_{1313} = -3(p^2 + \delta_S^2) k_S - 3(p - \delta_I)^2 k_I - 4(p - \delta_I)^2 k_0 - 6p^2 k_+ - p^2 k_- - Z_{1313}$	
$R_{2424} = -3(p^2 + \delta_S^2) k_S - 3(p + \delta_I)^2 k_I - 4(p + \delta_I)^2 k_0 - 6p^2 k_+ - p^2 k_- - Z_{2424}$	
$R_{3434} = -3(p^2 + \delta_I^2) k_I - 3(p + \delta_S)^2 k_S - 4(p + \delta_S)^2 k_0 - 6p^2 k_+ - p^2 k_- - Y_{3434}$	
Zero/multiple quantum	
$R_{2323} = -3(p^2 + \delta_I^2) k_I - 3(p^2 + \delta_S^2) k_S - 4(\delta_I - \delta_S)^2 k_0 - 2p^2 k_- - X_{2323}$	
$R_{1414} = -3(p^2 + \delta_I^2) k_I - 3(p^2 + \delta_S^2) k_S - 4(\delta_I + \delta_S)^2 k_0 - 12p^2 k_+ - X_{1414}$	
$p = \gamma_I \gamma_S \mu \hbar / 8\pi r_{IS}^3$	
$\delta = \frac{1}{3} \gamma B_0 [\sigma_{33} - \frac{1}{2}(\sigma_{11} + \sigma_{22})]$	
$k_0 = \frac{1}{5} \tau_c$	
$k_i = \tau_c / 5(1 + \omega_i^2 \tau_c^2)$	
$\omega_+ = \omega_I + \omega_S$	
$\omega_- = \omega_I - \omega_S$	

1. Pulse widths must be calibrated and accurate to within about 5% of ideal.
2. Data from the first part of the relaxation curve should not be used in the least-squares fit.
3. The transmitter should be as close to on resonance as possible to eliminate off-resonance effects.
4. Amplitudes of the spin echoes must be calculated relative to an experimentally determined steady-state value.
5. The sample should remain static so that the gradients in the magnetic field are not time-dependent.
6. Refocusing pulse spacings should be less than approximately 100 ms so that diffusion effects are eliminated.

Another method of measuring relaxation in the transverse plane is the spin locking experiment,^{19,20} in which one employs a continuous B_1 field in lieu of the sequence of 180° pulses used in spin echo experiments. This field locks the magnetization along the applied axis in the transverse plane. By varying the duration of the spin locking period, one may fit the peak intensity versus time to a decaying exponential and obtain the spin-lattice relaxation time in the rotating frame, $T_{1\rho}$. For most liquid samples, $T_{1\rho}$ is essentially equivalent to T_2 .^{19,21}

To obtain information about the relaxation rates for zero and multiple quantum coherences, a number of different pulse sequences have been proposed.²² For heteronuclear spin systems, the following pulse sequence may be used to generate double quantum coherences:²³

$$\left. \begin{array}{l} I : 90_y^\circ - \frac{1}{2}\tau - 180^\circ - \frac{1}{2}\tau - 90_x^\circ - t_1 - \text{acquire} \\ S : 180^\circ - \frac{1}{2}\tau - 90^\circ - t_1 \end{array} \right\} \quad (6)$$

where $\tau = \pi/2J$. The purpose of the 180° pulses is to refocus the dephasing of the magnetization due to magnetic field inhomogeneities and chemical shifts and suppress the dependence of the transmitter offset frequency. Yang et al.²⁴ proposed using a similar pulse sequence with explicit pulse phasings to separate the zero and double quantum coherences. This sequence is as follows:

$$\left. \begin{array}{l} I : 90_1^\circ - \frac{1}{2}\tau - 180_y^\circ - \frac{1}{2}\tau/2 \quad 180_x^\circ - \frac{1}{2}t_1 - 90_2^\circ \\ S : 180_y^\circ - \frac{1}{2}\tau - 90_y^\circ - \frac{1}{2}t_1 - 180_x^\circ - \frac{1}{2}t_1 - \text{acquire}_3 \end{array} \right\} \quad (7)$$

To obtain purely zero quantum coherence, the relative phasing of the pulses is

$$\left. \begin{array}{l} (1) \ x \ x \ -x \ -x \\ (2) \ x \ y \ x \ y \\ (3) \ x \ y \ -x \ -y \end{array} \right\} \quad (8)$$

which is arranged to eliminate any magnetization from the S spin. The recovery curve may then be fit to the following equation to obtain the zero quantum relaxation time T_{ZQ} :

$$\begin{aligned} I(t_1) &= I(\infty) + B'e^{-t_1/T_{ZQ}} \sin(\pi J \tau) \\ &= A + B'e^{-t_1/T_{ZQ}} \end{aligned} \quad (9)$$

To obtain purely double quantum coherence, the relative phasing of the pulses is

$$\left. \begin{array}{l} (1) \ x \ x \ -x \ -x \\ (2) \ x \ -y \ x \ -y \\ (3) \ x \ y \ -x \ -y \end{array} \right\} \quad (10)$$

The recovery curve may then be fit to an equation similar to that for a zero quantum coherence to obtain the double quantum relaxation time T_{DQ} .

3 APPLICATION TO MOLECULAR STRUCTURE AND DYNAMICS IN Na_2PHO_3

It is important to test the development of a new theory by carrying out experiments on a sample for which one knows the experimental results. All of the pertinent NMR parameters for a sample of Na_2PHO_3 have been measured by a number of independent methods. We therefore decided to carry out a set of transverse relaxation experiments with a solution of sodium phosphite, Na_2PHO_3 , dissolved in a 60%/40% mixture of ethylene glycol- d_6 and methanol- d_4 . They were performed at -25.4°C , a temperature slightly higher than the temperature of the proton-decoupled T_1 minimum of the phosphorus nuclei at a field of 4.7 T. Figure 2 shows the ^{31}P NMR spectra of the sample in a field of 11.5 T. The upper trace was recorded at 300 K, the middle trace at 250 K, and the bottom trace at 225 K. At 225 K, the low-frequency line has become so broad that it has disappeared into the baseline noise.

Fitting the data to equation (1) produced the following best fit parameters: the P-H bond length $r = 150.4$ pm, the proton chemical shift anisotropy $\Delta\sigma_H = 5.3$ ppm, the phosphorus chemical shift anisotropy $\Delta\sigma_P = -137.5$ ppm, the rotational correlation time, assuming a Lorentzian spectral density function, $\tau_c = 818$ ps, the phosphorus intermolecular term $A = 0.27\text{ s}^{-1}$, and the proton intermolecular term $B = 0.22\text{ s}^{-1}$. The theoretical transverse relaxation times may be calculated using these molecular parameters and the equations given in Table 1. Independent values for the P-H bond length were obtained from X-ray and neutron diffraction experiments.²⁵ Independent values for the phosphorus and proton chemical shift anisotropies were obtained from NMR

Figure 2 The ^{31}P NMR spectra of a sample of Na_2PHO_3 in a magnetic field of 11.5 T (202 MHz resonance frequency for phosphorus). The upper trace was recorded at 300 K, the middle trace at 250 K, and the bottom trace at 225 K. At 225 K, $\omega_0\tau_c \sim 1$, and the low-frequency line has become so broad that it has disappeared into the baseline noise

experiments on a solid sample of Na_2PHO_3 (T. C. Farrar, unpublished results).

These results show clearly that the two lines in the phosphorus spectrum will have different widths and the two lines in the proton spectrum will have different widths. The width of the $(1 \rightarrow 2)$ phosphorus line in PHO_3^{2-} must be broad, since the sign of the phosphorus CSA is negative and R_{1212} contains terms with the difference between δ_P and p . Similarly, the width of the $(3 \rightarrow 4)$ phosphorus line must be narrow, since R_{3434} contains terms with the sum of the CSA and dipolar terms. In the phosphorus spectra shown in Figure 2, the low-frequency line is broad; consequently, the sign of the phosphorus–proton coupling constant $J(\text{P,H})$ must be positive. The equations for R_{ijij} above also show that the greatest differential line broadening will occur at that field for which the CSA and the dipolar parameters are approximately equal, and under those sample conditions for which $\omega\tau_c \sim 1$. This is exactly what we have found experimentally.

The theory clearly tells us what to expect, but it is always a bit more satisfying if one can obtain a simple physical picture of what is happening. Consider, then, a single crystal of Na_2PHO_3 with the various orientations shown in Figure 3(a). The resonance frequency for the phosphorus nuclei that are bonded to protons will change as a function of Θ in the following manner:

$$f_\alpha = f_0 - \frac{\gamma_H \gamma_P \hbar}{r^3} (3 \cos^2 \Theta - 1) \quad (11)$$

$$f_\beta = f_0 + \frac{\gamma_H \gamma_P \hbar}{r^3} (3 \cos^2 \Theta - 1) \quad (12)$$

where f_α and f_β are the two frequencies in the phosphorus spectrum, Θ is the angle between the P–H internuclear vector and the magnetic field $\mathbf{B}_0$, and r is the P–H bond length. The other constants are defined in Table 1. Note that the f_α line arises from that half of the molecules in which the phosphorus is bonded to a proton nucleus in the α spin state (i.e., those proton nuclei that have their spins aligned parallel with the magnetic field $\mathbf{B}_0$), and the f_β line arises from that half of the molecules in which the phosphorus is bonded to a proton nucleus in the β spin state. If the chemical shift of the phosphorus is isotropic ($\delta_P = 0$), there will be a maximum splitting of $2p$ (about 15 kHz) for the two lines at a value of $\Theta = 0$. For $\Theta = 54.7^\circ$ (the ‘magic angle’), the two lines will coalesce, and at $\Theta = 90^\circ$ the splitting is p (about 7.5 kHz, see the definition of p in Table 1). The spectra for these orientations are depicted in Figure 3(a). The hatched lines below the spectra show the total variation in the magnetic field at the phosphorus nuclei as Θ varies.

If the phosphorus and/or proton chemical shifts are anisotropic (which they are for PHO_3^{2-}) then the local field experienced by the phosphorus nuclei will be very different. Figure 3(b) shows the single crystal spectra for the phosphorus for the same orientations as in Figure 3(a). The frequencies of the two lines are now given by

$$f_\alpha = f_0 - \frac{\gamma_H \gamma_P \hbar}{r^3} (3 \cos^2 \Theta - 1) + \delta_P (3 \cos^2 \Theta - 1) \quad (13)$$

$$f_\beta = f_0 + \frac{\gamma_H \gamma_P \hbar}{r^3} (3 \cos^2 \Theta - 1) + \delta_P (3 \cos^2 \Theta - 1) \quad (14)$$

Figure 3 (a) ^{31}P NMR spectra for a single crystal of Na_2PHO_3 at three different orientations of Θ , the angle between the P–H internuclear vector and the magnetic field direction, assuming a phosphorus CSA of zero. (b) As (a), but with a phosphorus CSA value of -140 ppm

If the magnitudes of the phosphorus dipolar and CSA terms are about equal then one of the lines in the single crystal spectrum will experience almost no change in frequency as a function of Θ , since any change in the local field due to the dipolar term will be canceled by the CSA term. The other line will experience a change almost twice as great, since local fields generated by the dipolar and CSA terms add constructively. For PHO_3^{2-} , the phosphorus CSA, $\delta_P = (\sigma_{\parallel} - \sigma_{\perp})_P = -125$ ppm.^{6,7} In this case, the total range of magnetic fields experienced as a function of Θ is very small for the P_β nuclei, the phosphorus nuclei spin-coupled to proton nuclei in the β spin state. At a magnetic field of about 6.3 T, the local magnetic field for the P_β nuclei is almost independent of orientation. For the P_α nuclei, the local field changes over a range almost twice as great as that expected for the dipolar interaction. In other words, the dipolar field fluctuations at the P_β nuclei due to changes in orientation are largely canceled by field changes of the opposite sign due to the CSA. The hatched bars below the spectra in Figure 3(b) show schematically this very small range in the local field for the P_β nuclei and the twofold greater-than-normal dipolar range in the dipolar field for the P_α nuclei.

When the molecules begin to move, the magnetic fields at the P_α and P_β nuclei are modulated by the molecular motion. And it is the magnitude of this motion-induced magnetic field modulation [represented by the hatched bars in Figure 3(a) and (b)] that couples the precessional motion of the nuclear spins to the molecular motion and brings about relaxation of the nuclear spin system. When the CSA and dipolar interactions are comparable, as they are in the present case, relatively little magnetic field modulation occurs at the P_β nuclei. Consequently, they will have a very long relaxation time, even for slow molecular motions where $\omega_P \tau_c \sim 1$. The P_α nuclei, however, will experience much larger than normal magnetic field fluctuations, and as a result will have short relaxation times.

Normally, one cannot determine which of the lines in a high-resolution NMR spectrum are associated with the transitions between the various energy levels. For example, in a spectrum such as that in Figure 2, it is not usually possible to determine whether the high-frequency phosphorus line arises from the transition between energy levels 1 and 2 or between levels 3 and 4. However, when differential line broadening is present, one can easily determine which line is associated with the transitions between the energy levels. As pointed out above, since we know from solid state NMR experiments that the phosphorus CSA is negative and since we know from the spectrum that it is the low-frequency phosphorus line that is broad, by looking at the expression for R_{1212} above, we know that the broad line must be associated with the R_{1212} transition. Consequently, the absolute sign of the phosphorus–hydrogen spin coupling constant, $J(\text{P,H})$ must be positive; in this case, $J(\text{P,H}) = +565$ Hz. In a similar fashion, we have shown that the absolute sign of directly bonded carbon–hydrogen spin coupling is positive.⁸

The transverse relaxation times for all four lines were measured using the CPMG sequence [see equation (5)] and $T_{1\rho}$ experiments. The experiments were performed on resonance at the same temperature as the longitudinal relaxation experiments. The sample was static, and field/frequency locking was not used. A three-parameter fit to an equation similar to equation (9) gives the transverse relaxation time. For the $R_{1\rho}$ experiments, the spin locking fields γB_1 were 340 and 746 s^{-1} , respectively, for the proton and phosphorus nuclei. Table 2 shows a comparison of the results from these experiments.

4 DISCUSSION

Examining Table 2, one sees that the experimentally determined transverse relaxation times do not agree with the theoretical relaxation times calculated from the bond length, the two CSAs, and the correlation time obtained from the longitudinal relaxation studies. The calculated T_{ij} values are appreciably longer than the experimentally determined values. The differences are due to several factors. The largest source of the differences probably arises from the intermolecular, random field terms. These terms account for relaxation mechanisms of rank one, such as scalar relaxation, spin rotation, chemical exchange, and relaxation due to the presence of paramagnetic species. Since the experiments were done at low temperature, spin rotation can be ruled out. Very careful sample preparation allows one also to rule out paramagnetic impurities. Since the random field terms for

the longitudinal relaxation also contribute to the transverse relaxation, and have been included in the Y_{ijj} and Z_{ijj} terms in the calculated values, the difference must arise from additional random field terms that are unique to the transverse relaxation. Such terms would include those due to chemical exchange and other relatively slow random dynamic processes. Neglect of these terms will result in calculated values for the transverse relaxation rates that are smaller (and calculated relaxation times that are longer) than the experimentally measured values.

If one assumes that the additional intermolecular contribution is the same for both single quantum coherences of a given nucleus, one may subtract the relaxation rates and get a relation independent of the intermolecular interactions:

$$\Delta_P = R_{1212} - R_{3434} = 12p\delta_P k_P + 16p\delta_P k_0 \quad (15)$$

$$\Delta_H = R_{1313} - R_{2424} = 12p\delta_H k_H + 16p\delta_H k_0 \quad (16)$$

where k_i and k_0 are defined in Table 1. Comparing the experimentally obtained values of these parameters with those calculated from T_1 data, the results still do not agree, implying either that these additional intermolecular terms are not the sole factor causing the difference or that there are still additional random field terms operating that do not equally affect the two different coherences for a given nucleus. This suggests, for example, that Y_{1212} and Y_{3434} (see Table 1) are not equal.

Another factor that may lead to the discrepancies seen between the theoretical relaxation rates and the experimentally determined rates is the form of the spectral density function. Longitudinal relaxation depends on rapidly fluctuating fields near the Larmor frequency γB_0 . Transverse relaxation times depend on fluctuating fields near the Larmor frequency as well as slowly fluctuating fields described by k_0 . The Lorentzian spectral density function may not be valid for this range of molecular motions. Finally, the experiments may not be measuring the true transverse or zero/multiple quantum relaxation rates.

5 SUMMARY

In principle, transverse relaxation studies, including zero and multiple quantum coherences, can provide structural and dynamic information. They complement longitudinal relaxation studies in that they provide information concerning low-frequency motions and cross-correlation functions. Preliminary work comparing longitudinal and transverse relaxation results obtained for PHO_3^{2-} in solution indicates that great caution
